Diatom abundance is much used as an indication of past surface productivity, but DAR represents a more reliable measure to assess productivity estimations. In terms of diatom assemblages, coastal upwelling systems have similar assemblages, not only in the water column, but also in the sediment record, at least in respect to the dominant species. The high contribution to the assemblage of the chain-forming *Chaetoceros* reflects bloom conditions. *Chaetoceros* is an opportunist genus known to respond very fast to nutrient pulses and water turbulence. Its capacity to produce RS results in a good sedimentary record of coastal upwelling conditions. But the genus is also abundant in the North Atlantic where their spring blooming reflects nutrient availability and ideal light conditions.

Equatorial upwelling regions have a totally different diatom assemblage from the coastal zones, but there is not much difference between Pacific and Atlantic diatom assemblages. The genus *Thalassionema* Grunow is the dominant taxon found in sediment assemblages, with contributions of the upwelling-related fragile forms of *Pseudo-nitzschia* Peragallo and *Nitzschia* Hassall.

In the high northern latitudes of the open ocean, diatom assemblages contain largely endemic species. In the north Pacific, *Neodenticula* Akiba and Yanagisawa, together with several species of *Rhizosolenia* Ehrenberg, *Thalassiosira* Cleve, and *Coscinodiscus* Ehrenberg, dominates the assemblages. In the North Atlantic, *Neodenticula* is not present, and *Thalassiosira gravida* Cleve and *Thalassionema nitzschioides* (Grunow) Mereschkowsky are the dominant.

In the SO, at least five species are unique to Antarctica: *F. kerguelensis* (O'Meara) Hustedt, *Eucampia balaustium* Castracane, *Thalassiosira lentiginosa* (Janish) Fryxell, *C. margaritae* Freguelli, and *Thalassiosira gracilis* (Karsten) Hustedt.

Time series of DAR and assemblage composition from the Atlantic major coastal upwelling loci of the eastern boundary currents and eastern equator indicate glacial periods as the most productive times in both hemispheres of the eastern Atlantic. An increase in PP was also found in the Angola Basin and attributed to the northern penetration of a stronger Benguela current. A more vigorous atmospheric circulation, intensifying the trade winds and the wind-driven equatorial divergence, could explain this general increase in PP in the glacial Atlantic (Figure 4).

In the SE Pacific, productivity does not vary in consonance with glacial–interglacial cycles. At the Peru margin, variability in paleoproductivity occurs across oxygen isotope boundaries; off the coast of Chile, productivity is higher during glacials.

In the NW Pacific and the NE Pacific upwelling margin, diatom records point to a decrease in productivity during glacials and increase in interglacials.

Studies have also been performed on sediments underlying HNLC regions: the SO and the equatorial Pacific. An excess of Si in the glacial Antarctic, as a result of dust Fe input during glacials, was hypothesized in the 1990s. The northward transport of that Si to low- and mid-latitudes by the sub-Antarctic mode waters would generate a floristic change from coccolithophores to diatoms, resulting in the lowering of atmospheric $p\text{CO}_2$.

Changes in productivity in phase with inputs of Fe from the continent, reported off the coast of Chile, may provide the link between past changes of iron availability and biological productivity.

In the HNLC equatorial Pacific, which has also been shown to be an Si-limited ecosystem, downcore studies of benthic Foraminifera indicate higher productivity in the glacials, while diatoms increase in the interglacials.

An apparent contradiction between productivity proxies is found in the SO, where most of the biogenic opal burial occurs at present under the Antarctic Circumpolar Current (ACC). Assuming the observed HNLC conditions are a consequence of Fe limitation and that the Fe supply results in thinner diatom valves, the supply of Fe to the oceans can increase diatom carbon export to the seafloor without enhancing biogenic Si export. Furthermore, an increase in diatoms in sedimentary sequences from the open south Atlantic, located 6° N of the present Polar front, as well as a suite of 50 cores from the Atlantic and western Indian sector, suggests a northward expansion of the sub-Antarctic front by 5–6° in latitude. However, the contradiction reappears when diatom-bonded $\delta^{13}\text{C}$ and $\delta^{29}\text{Si}$ data point to no increase in productivity, nor in the percentage of Si utilization by diatoms during the last

Figure 4 (a) Cores' approximate location on a 3-month composite coastal zone color scanner estimates of phytoplankton pigment concentration (June–July 1979 to NSF/NASA 1989). (b) DARs (number of valves $\text{cm}^{-2} \text{ka}^{-1}$) versus age (^{14}C ka) along the cores retrieved from the major coastal upwelling areas of the eastern Atlantic (KS11 – Portugal; GeoB M1410 – Canary Islands; M13229 – Cape Blanc; GeoB M1710 – Walvis Bay.). Reproduced from Abrantes F (2000) 200 000 yr diatom records from Atlantic upwelling sites reveal maximum productivity during LGM and a shift in phytoplankton community structure at 185 000 yr. *Earth Planetary Science Letters* 176: 7–16.

glaciation, relatively to the Holocene. According to Dugdale et al. (2004), the teleconnection for nutrients between the equatorial Pacific and Antarctica suggests an oscillatory relationship that may influence or control the Si glacial cycles. This hypothesis connects to the silica leakage hypothesis (SALH) that Matsumoto et al. (2002) have invoked to explain the drawdown of atmospheric CO₂ during glacial intervals. However, this has been challenged by Bradt Miller et al. (2009) who found convincing evidence for SALH in the equatorial Atlantic but not in the Pacific. However, large increases in Si in Pacific sediments in some terminations and other periods suggest that the SO might not be the only source for silica.

Millennial variability

Several workers have shown the dramatic climatic variability, known as Dansgaard–Oeschger (D–O) cycles, in Greenland ice cores and in many marine sequences. The largest D–O oscillations, known as Heinrich events (HE), are believed to represent major iceberg discharges in the North Atlantic and are associated with a southern invasion of polar waters, disruption of the North Atlantic current circulation, and decrease in deep-water ventilation. The relation between oceanic productivity and these major climatic variations has been assessed by diatom quantification for HE1 and HE4 through the open North Atlantic, from north to south of the iceberg discharge belt (the Ruddiman belt). During HE4, diatom productivity decreased drastically at all latitudes, but throughout HE1, productivity increased in the Sargasso Sea (Gil et al., 2009) and apparently was not affected in northern latitudes, possibly due to the associated increase in summer insolation not observed during H4 (Nave et al., 2007).

Productivity variations have also been assessed for the anoxic Cariaco Basin laminated sediments, from the analysis of CSE for the Bølling/Allerød–Younger Dryas (YD) interval. Diatom populations increased during the YD in the Cariaco Basin, reflecting a higher productivity attributed to a regional intensification in trade winds and upwelling.

Centennial to decadal variability

Centennial-scale variability in productivity, temperature, and trajectory of water masses, associated with the most recent Holocene climatic shifts: the Little Ice Age and the Medieval Warm Period, are also revealed by diatom abundance and assemblage composition in high-sedimentation rate cores from the NW and NE Atlantic margins. At present, the North Atlantic oscillation (NAO) is believed to dictate climate variability across most of the Northern Hemisphere, especially during wintertime. Those diatom records are, at all sites, coherent with the action of a NAO-like mechanism or the NAO itself.

One promising proxy for the reconstruction of El Niño events through time is *A. nodulifera*, an open ocean tropical form that reaches the Peruvian and California coasts and has a major flux to the bottom during such events. Besides, its spatial distribution in the Peruvian coastal sediments marks the area where unusually warm waters are registered in El Niño years. In a 15-ka record from the Guayama Basin, this species abundance reveals that modern oceanographic conditions with intensified ENSO cycles was established between 2.8 and 2.4 ka

and 500–200-year cycles of more frequent and/or stronger El Niño-like events (Barron et al., 2004).

Monospecific mats

In addition to the spring bloom and upwelling productivity, large diatoms, typical of oligotrophic areas, are capable of generating substantial production that may contribute significantly to the biological pump.

A long line of diatom-rich waters was spotted in the equatorial Pacific by the space shuttle crew, and subsequent *in situ* sampling revealed a rhizosolenid mat along a thermal front that corresponded to a tropical wave instability. These mats can remain in the surface waters until changes in wind circulation or loss of buoyancy due to physiological stress causes them to sink to the ocean bottom where they form a thick and unbreakable net that prevents sediment bioturbation.

Quaternary mat deposits have been recognized beneath major frontal regions in the North Atlantic and SO (Figure 5). Other examples come from the Benguela current upwelling system, where a mat deposited from 2.6 to 2 Ma may reflect

Figure 5 A 3-m diatom mat composed of billions of layers of the hairlike diatom *Thalassiothrix longissima* found in the North Atlantic. (a) Section of the split core showing the layers (or laminae); (b) fibrous diatoms; and (c) scanning electron microscope photomicrograph showing the sheet of paper like individual mats of diatoms http://www.log.furg.br/WEBens/ideo/CORE_REPOSITORY/RHP4Boden.html. Reproduced from Bodén P and Backman J (1996) A laminated sediment sequence from the northern north Atlantic Ocean and its climatic record. *Geology*, 24, 507–510.

an increased influence of SO water on the SE Atlantic. In the inner continental shelf basins of the Western Antarctica Peninsula, a *Chaetoceros*-dominated ooze was found in laminated sediments deposited during the last deglaciation, representing increased PP. Rhizosolenid-laminated sediments were also described in the eastern Mediterranean and related to density variations in the water column resulting from variations in the Nile river input. Analogous oozes of the giant diatom *Ethmodiscus rex* Castracane were described in the equatorial Atlantic and at 9° S in the Indian Ocean.

General circulation

Many water column diatom assemblages show close affinity to water masses and help to trace past positions and interactions between water masses and current systems. Downcore assemblage studies defined on a regional level were successfully used as paleoceanographic indicators in many cases: in the Norwegian Sea, revealing variations in the influx of temperate Atlantic surface waters during the Holocene, and in the north Icelandic shelf, revealing interactions between the cold East Greenland Current and the warm Irminger Current during the latest Holocene. In the Gulf of St. Lawrence, deglaciation and Holocene diatom data support the suggestion that the YD cooling event could not have been caused by meltwater input from the Laurentide ice sheet. In the ACC (at a site that lies immediately downstream from where North Atlantic Deep Water (NADW) is entrained into the ACC), deglacial submillennial-scale variations in the numbers of *Chaetoceros* RS are related to shifts in the path of the ACC and in the strength of NADW overflow in the Falkland Plateau and document important interhemispheric links between the North Atlantic and the SO (Allen et al., 2005).

Sea ice dynamics

The presence in the sediments of *Eucampia antarctica* (Castracane) Mangin, a species that lives at the ice margin in Antarctica, has been used as a tracer for Antarctic sea ice. Another group of diatoms live in brine pockets at the base of sea ice in both the Arctic and the Antarctic (Figure 6). These diatoms bloom twice a year, within the ice in spring and in the ocean in summer, which leads to different species in each bloom and generates a transition in species composition between the ice margin and the open ocean. Tracing these two assemblages in the surface sediments allowed the

Figure 6 View of a pack of sea ice at Terra Nova Bay in January of 1990, where a brownish-colored band due to the presence of high numbers of diatoms is clearly visible. Photograph by Caterina Nuccio.

estimation of a more reduced summer sea ice field during the Last Glacial Maximum.

Furthermore, the presence of Quaternary diatoms in glacial sediment samples recovered from beneath the West Antarctic ice sheet (grounded ice) and their correlation with beryllium-10 dates imply one or more partial (Ross Sector) or complete marine ice sheet collapse events in interglacials of the past 750 ka.

Lateral transport/displacement

Displaced diatoms can provide important paleoecological information. The presence of benthic marine diatoms in deep sediments (>200 m) indicate lateral displacement of shallower sediments. Lateral advection can be traced by the planktonic neritic taxa normally present in highly productive coastal regions but found offshore, when live specimens are laterally advected by upwelling filaments. The distribution of Antarctic endemic diatoms in the sediments of the Pacific and the southwest Indian Ocean reveals the northward path of Antarctic bottom water, as far as the equatorial regions.

Sea-level variability and other coastal processes

Marine littoral diatoms can be used to reconstruct sea-level changes in the recent past.

Many of these species, which are similar throughout the world, show tidal zonation; as such, changes in diatom community indicate past sea level. Diatom TF have been developed and successfully applied to reconstruct sea-level changes in arctic (Woodroffe and Long, 2010) and tropical environments. These data help address a variety of problems in coastal geology (paleogeography, natural hazard assessment).

Diatoms as Tracers of Continental Climate

Freshwater diatoms can also be found in deep-sea cores, and their presence in atmospheric dust off NW Africa allows their use as tracers of the path and intensity of past storms. Off Africa, the Sahel and sub-Saharan intermittent lakes are the dust source. In the equatorial Atlantic, freshwater diatom records have made it possible to determine the time of the first influx of wind-blown continental detritus (1.2 Ma). Over the last 900 ka, peaks in the abundance of the freshwater diatom *Aulacoseira granulata* were found in equatorial Atlantic cores between 3° N and 1° S and 21° to 25° further N, with a periodicity that corresponded to the Earth's precession cycle and related to African monsoon cycles.

In Greenland ice cores, layers of freshwater diatoms parallel those of smaller dust particles and are related to seasonal winds originating from dry areas of North America. In central Antarctic ice cores, freshwater and marine diatoms occur in smaller abundances than in Greenland, but their downcore pattern follows the dust data with higher concentrations during glacial periods (Kellogg and Kellogg, 1996). Their origin was traced to Patagonia.

Regarding a more quantitative approach to the freshwater diatom signal in marine sediments, Lopes et al. (2010) developed a linear equation calibrated with modern conditions that allowed the identification and dating of undisturbed marine material, linked with the Glacial Missoula flood signal.

Biostratigraphy

Biostratigraphy is only possible because species evolve and become extinct at specific times, and the evolution of one species is not repeatable. Diatoms are particularly advantageous for biostratigraphic studies of high-latitude sediments where calcareous microfossils are often poorly preserved or of low diversity.

With the advent of the Deep Sea Drilling Project, many kilometers of sediment cores have been recovered, and it has been possible to determine that the evolutionary history of diatoms has been punctuated by several floristic turnovers. But, recognition of diatoms as biostratigraphic tools by the geologic community came only when Burckle (1972) correlated late Cenozoic diatoms from the equatorial Pacific to the same site magnetic polarity zonations.

The bimodal size–frequency distribution of *A. nodulifera* in the equatorial Pacific allows size changes to be applied biostratigraphically in late Quaternary fossil assemblages from this region.

The first appearance of *Fragilariopsis doliolus* Husted, a species mainly from equatorial regions but present up to 40° from the equator, marks the beginning of the Quaternary in marine records. By the early Quaternary, the modern diatom flora was developed in most marine environments.

Planktic Foraminifera

H J Dowsett and M M Robinson, US Geological Survey, Reston, VA, USA

© 2013 Elsevier B.V. All rights reserved.

Description

Planktic Foraminifera are single-celled eukaryotic organisms that live in the photic zone of the marine environment and exhibit passive floating lifestyles (Figure 1(a)). They range in size from 100 to 1 mm in length and gain nutrition by capturing food particles and digesting them within their protoplasm. Many species also carry symbiotic algae within their protoplasm that photosynthesize during the day. Planktic Foraminifera (often referred to as planktic forams) secrete shells (tests) composed of calcium carbonate (CaCO_3) that are usually characterized by a number of chambers added during growth. Individuals are thought to reproduce about every 28 days with the lunar cycle and may live up to a few months, after which their tests sink to the ocean floor. Approximately 40 species of planktic Foraminifera live in the ocean today. This comprises about 1% of the extant species of Foraminifera (99% are benthic).

Historical Background

The geologic record of Foraminifera begins in the earliest Cambrian. Foraminifers probably existed as cells without tests long before that. At ~200 Ma, during the Jurassic, some foraminifers adapted to a planktic mode of life. The rapid evolution of planktic Foraminifera during the Cretaceous and throughout the Cenozoic makes them ideal biostratigraphic markers, and their sensitivity to physical and biological environmental changes makes them useful indicators of paleoceanographic and paleoclimatic history.

Prior to the advent of the microscope, seventeenth century naturalists observed foraminifers with hand lenses and often classified them as gastropods or cephalopods because many possess a coiled-chamber arrangement. As microscopy advanced, more detail in the structure of tests was observed, and Foraminifera were recognized as single-celled organisms. The first detailed descriptions of planktic Foraminifera were published by d'Orbigny (1826). Foraminiferal studies advanced with the sailing of the *Challenger* expedition of 1872–76. Brady (1884) illustrated a number of planktic foraminifers from this first oceanographic cruise, and our understanding of planktic foraminiferal biogeography began to take shape. The next major advancement was the development of scanning electron microscopy, which enabled detailed analysis of test wall ultrastructure for the first time. The Deep Sea Drilling Project (DSDP) and its successors, the Ocean Drilling Program (ODP), and the Integrated Ocean Drilling Program (IODP), have provided a wealth of quantitative data on both the temporal, geographic, and paleoecologic distribution of planktic foraminifers.

Classification

The taxonomic classification of Foraminifera has proved problematic, with little consensus across the scientific community. For simplicity, the authors ignore the higher classification categories of the Linnaean system and adopt the well-known foraminifer classification scheme of Loeblich and Tappan (1988) which places planktic foraminifers into order Foraminiferida and suborder Globigerinida.

Traditionally, planktic foraminifers are classified primarily by the morphology and ultrastructure of their secreted calcium carbonate (CaCO_3) tests. The number, shape, and arrangement of chambers, the position and shape of apertures, and test ornamentation are important criteria (Figure 1(b)), reflecting a long history of study and utilization by micropaleontologists using optical microscopes. Because classification based solely on test morphology ignores phylogenetic relationships among species, most modern classification schemes incorporate the present understanding of ancestor–descendant relationships and the conservative morphologic features of lineages such as surface ultrastructure. Recent studies of foraminiferal rDNA sequencing have led to advances in molecular phylogeny, at times upsetting existing classification schemes.

Geographic Distribution of Living Planktic Foraminifera

The geographic distribution of living planktic foraminifers at any instant in time depends upon a number of controlling conditions. Temperature and salinity are considered first-order controls, but nutrient concentrations at various depths in the water column, water density, CO_2 , O_2 , distribution of symbiotic organisms, predation, and food supply are also significant factors.

Planktic foraminifers live in the upper 200 m of the ocean at all temperatures, from the freezing point of seawater (approximately -1.8°C) to the warmest sea surface conditions near 31°C (Be, 1971). Extensive monitoring through plankton tows and sediment trap studies shows that different taxa live at different depths and that the vertical distribution of planktic foraminifers in the water column changes daily and seasonally. In general, species living very close to the sea surface (0–50 m) include *Globigerinoides ruber*, *Globigerinoides sacculifer*, *Globigerinoides conglobatus*, *Turborotalita quinqueloba*, and *Globigerina rubescens*. Deeper-dwelling planktic forams (>100 m) include *Globorotalia crassaformis*, *Globorotalia inflata*, *Globorotalia tumida*, *Globorotalia menardii*, *Globorotalia truncatulinoides*, *Neoglobobulimina pachyderma*, and *Sphaeroidinella dehiscens*.

Present-day planktic foraminifers are arrayed in generally zonal assemblages (polar, subpolar, temperate, subtropical, and tropical) that are globally distributed and bipolar in nature

Figure 1 (a) Light micrograph of the living Foraminifera, *Orbulina universa*, with its final spherical chamber surrounding an internal multichambered shell (dark cytoplasm filled region within the sphere). Numerous symbiotic dinoflagellates form a spherical region of photosynthetic activity around the shell (golden color). The calcite spines typically extend 2.0–2.5 mm beyond the surface of the shell that is 0.5 mm in diameter. Courtesy of Dr. Howard Spero, Department of Geology, University of California at Davis. (b) Line sketches of common species showing a variety of chamber arrangements. (1) *Globigerinella aequilateralis*; (2) *Neogloboquadrina dutertrei*; (3) *Globigerinita glutinata*; (4) *Neogloboquadrina pachyderma* (dextral); (5) *Turborotalita quinqueloba*; (6) *Globigerinoides ruber*; (7) *Globigerinoides sacculifer*; (8) *Globorotalia truncatulinoides*; and (9) *Globorotalia menardii*.

Figure 2 Geographic distribution of living planktic Foraminifera grouped by biogeographic assemblages.

(Figure 2). The polar regions are characterized by nearly monospecific assemblages composed of *N. pachyderma*. These polar assemblages sometimes contain minor concentrations of *T. quinqueloba*, *Globigerina bulloides*, and *Globigerinita glutinata*. Coiling direction of some taxa is significant, and the coldest regions are occupied almost exclusively by sinistrally (left) coiling forms of *N. pachyderma*.

Subpolar waters are characterized by *Globigerina bulloides*, dextrally coiling *N. pachyderma*, *T. quinqueloba*, *Globorotalia inflata*, *Globorotalia truncatulinoides*, *Globorotalia scitula*, and *Globigerinita glutinata*.

Species diversity in general increases toward the tropics where a typical open ocean assemblage comprises 25–30 different species of planktic Foraminifera including

Globigerinoides sacculifer, *Globigerinoides ruber*, *Globigerinoides conglobatus*, *Globorotalia menardii*, *Globorotalia tumida*, *Globorotalia crassaformis*, *Globorotalia truncatulinoides*, *Globigerina rubescens*, *Globigerina bulloides*, *N. dutertrei*, *Globigerinella aequilateralis*, *Globigerinita glutinata*, *Orbulina universa*, *Candeina nitida*, *S. dehiscens*, and *Pulleniatina obliquiloculata*. These low-latitude assemblages are dominated by *Globigerinoides ruber* and *Globigerinoides sacculifer*. Both taxa have maximum abundance in the tropics, but *G. sacculifer* is euryhaline and an excellent indicator of high-salinity conditions.

The subtropical assemblage contains *Globigerinoides ruber*, *Globigerinoides sacculifer*, *Globigerinoides conglobatus*, *Globorotalia menardii*, *Globorotalia inflata*, *Globorotalia truncatulinoides*, *Globorotalia hirsuta*, *Globigerina falconensis*, *Globigerina bulloides*,

N. dutertrei, *Globigerinella aequilateralis*, *Globigerinita glutinata*, *Globorotalia crassaformis*, and *O. universa*.

The temperate assemblage exists at the gradient between the subtropical warm waters and subpolar cool waters. It is characterized by a mixed assemblage containing both cool and warm water taxa.

Seafloor Distribution of Planktic Foraminifera Tests

The seafloor thanatocoenosis (death assemblage) is the result of complex interactions between foram tests and the biological, chemical, and physical environment. Despite minor differences between plankton tow or sediment trap observations and core top assemblages, there exists a robust and overwhelming surface temperature signal in the quantitative distribution of planktic foraminifera on the seafloor. This fact has been utilized by paleoceanographers to help unlock the Quaternary history of the world's oceans. For example, during glacial periods, the range of polar and subpolar assemblages expanded, relative to today, and shifted in their geographic distribution toward the equator (CLIMAP, 1981; MARGO, 2009).

Stratigraphic Distribution and Biostratigraphy

The combined characteristics of high abundance, small size, facies independence, ease of identification, and high preservation potential make planktic foraminifera ideal for biochronological analyses. For any pre-Quaternary study, foraminiferal biochronology remains one of the leading age-dating tools in terms of accuracy and utility. Planktic foraminifera zonation have been developed by a number of workers, and individual

events (biotic first appearance datums (FAD) and last appearance datums (LAD)) have been dated by calibration to magnetostratigraphy (e.g., Berggren et al., 1985, 1995a; Dowsett, 1989; Wade et al., 2010) and oxygen isotope stratigraphy (Berggren et al., 1995b). Within the Quaternary, there are relatively few evolutionary events that can be used for foram biostratigraphy.

The most widely used tropical to subtropical planktic foraminifera zonation (Berggren et al., 1995a modified by Wade et al., 2011) characterizes the Quaternary by one low-latitude zone, Pt1 or the *Globorotalia truncatulinoides* partial range zone. Pt1 is defined as the interval containing *Globorotalia truncatulinoides* between the highest occurrence of *Globigerinoides fistulosus* and the recent. The last appearance of *Globigerinoides fistulosus* is approximately synchronous (~1.88 Ma) in both Atlantic and Pacific tropical sites. The first appearance of *Globorotalia truncatulinoides* is generally synchronous outside the South-West Pacific region at ~1.8 Ma (Figure 3).

Pt1 can be subdivided into a lower Pt1a or *Globorotalia tosaensis* highest occurrence subzone (Wade et al., 2011). Pt1a is defined as the interval between the highest occurrence of *Globigerinoides fistulosus* and the highest occurrence of *Globorotalia tosaensis*. This zone has an estimated age of ~1.77–0.65 Ma. Pt1b or the *Globorotalia truncatulinoides* Partial range subzone is defined as the biostratigraphic interval characterized by the partial range of the nominate taxon following the highest occurrence of *Globorotalia tosaensis* and extending to the recent (Wade et al., 2011).

Stratigraphic information (summarized from Berggren et al. (1995b) and Wade et al. (2011)) shows the following planktic foraminiferal events to be useful for developing Quaternary biochronology: LAD *Globorotalia flexuosa* (0.068 Ma; $\delta^{18}\text{O}$ stage 4), LAD *Globigerinoides ruber* (pink) (0.12 Ma;

Figure 3 Quaternary (sub)tropical planktic foraminifer biostratigraphy and magnetobiochronology. After Berggren et al. (1995a,b) and Wade et al. (2010) and Benthic $\delta^{18}\text{O}$ from Lisiecki and Raymo (2005).

Indo-Pacific only), LAD *Globoquadrina pseudofoliata* (0.22 Ma; $\delta^{18}\text{O}$ stage 7), FAD *Globorotalia flexuosa* (0.401 Ma; $\delta^{18}\text{O}$ stage 11), FAD *Globorotalia hirsuta* (0.45 Ma; $\delta^{18}\text{O}$ stage 12), LAD *Globorotalia tosaensis* (0.65 Ma), FAD *Globorotalia crassaformis hessi* (0.75 Ma), FAD *Globorotalia truncatulinoides excelsa* (1.00 Ma), and LAD *Pulleniatina finalis* (1.40 Ma). A good overview of other planktic foraminifer zonal schemes and stratigraphic distribution of various taxa within the Quaternary can be found in Bolli et al. (1985).

One last biochronological application of planktic Foraminifera is based upon coiling direction changes. Some taxa (e.g., *Globorotalia truncatulinoides* and *N. pachyderma*), as indicated in the section on living Foraminifera, show a relationship between sea surface temperature (SST) and the ratio of sinistrally (left) to dextrally (right) coiled tests. In high-latitude cold regions, *N. pachyderma* exhibits sinistral coiling almost exclusively. In subpolar regions, more dextral-coiling specimens are observed. In local to regional settings, stratigraphic correlations can be based upon regular shifts in coiling patterns.

Applications to Paleoclimatology and Oceanic Paleoclimatology

With the recognition that the distribution of planktic Foraminifera on the seafloor closely matches overlying oceanic conditions, utilization of the ecological tolerances and preferences of extant taxa (taxonomic uniformitarianism) have been used both qualitatively and quantitatively to reconstruct past conditions.

The occurrence of warm-water taxa like *Globorotalia menardii* at latitudes far North or South of their present-day distribution is commonly used as evidence for warmer conditions. Likewise, the equatorward retreat of other taxa can signal cooling, relative to today. Quantitative analysis of assemblages of planktic foraminifera has been widely used to reconstruct past sea surface temperature using transfer function or nearest modern analog approaches.

Transfer functions range from simple (Ericson and Wollin, 1956) to the complex factor analytic approaches pioneered by Imbrie and Kipp (1971). This latter approach formed the basis of the CLIMAP Last Glacial Maximum reconstruction (CLIMAP, 1981) and has been modified and used to reconstruct paleoclimate conditions during other Quaternary intervals and even back to the mid-Pliocene (Dowsett et al., 2005, 2010).

Modern analog techniques were first introduced by Hutson (1979). Today there are many variations on the basic technique, but all are based upon statistical matching of a fossil sample (census) to a modern assemblage and assigning the physical characteristics (e.g., temperature) of the closest modern analog to the fossil sample.

Calcium carbonate tests are thought to be secreted in equilibrium with seawater at the time of formation. For this reason, planktic foraminifera have been the most widely used organisms for shell chemistry (e.g., Mg:Ca) and stable isotope geochemistry ($\delta^{18}\text{O}$, $\delta^{13}\text{C}$, etc.). In addition, planktic foraminifera are generally found in sufficient abundance for AMS ^{14}C dating. Their small size, abundance, and distribution make them ideal paleoenvironmental tools. With the knowledge that different species of planktic foraminifer live at different depths

and reach maximum abundance at different times of the year, geochemical analyses of planktic foraminifera tests can provide a wealth of information on the composition and structure of the water column in the past. With benthic foraminifera providing information on bottom waters, elaborate paleoenvironmental and paleoclimatic information can be mined from samples containing foraminifera.

In summary, planktic foraminifera are the original multi-tool for Quaternary marine studies. The quantitative distribution of foraminifera in both temporal and spatial dimensions provides information on the age of the sample and many aspects of the paleoclimatic environment. When combined with geochemical and isotopic analyses of planktic foraminifera tests, this fossil group surpasses all others in its contribution to the field of Quaternary paleoclimatology.

Radiolarians and Silicoflagellates

D Lazarus, Museum für Naturkunde, Berlin, Germany

© 2013 Elsevier B.V. All rights reserved.

Introduction

This article discusses the application of radiolarians and silicoflagellates to Quaternary studies. For the most part, the article discusses radiolarians, marine protist microzooplankton, whose siliceous shells are found in sediments as old as the Cambrian. Radiolarians are widely used in Quaternary stratigraphy and paleoceanographic research. Silicoflagellates are marine protist phytoplankton. Their shells, also of opaline silica, are uncommon in sediments but occur sporadically from early Cretaceous to the Recent, and have occasionally been used for stratigraphy and paleoceanographic purposes.

General books on radiolarians include Anderson (1983) on the group's biology and De Wever et al. (2001) on fossil forms. Boltovskoy et al. (2010) provide a synthesis of biogeographic and ecologic information for living species, while a reasonably comprehensive list of named living species is maintained online at WoRMS. A short general review of radiolarian research is provided by Lazarus (2005). Monographic length literature on silicoflagellates is essentially lacking, but short chapters by Perch-Nielsen (1985) (emphasizing biostratigraphy), Bukry (1995) and McCartney (1995) (emphasizing biology) provide a reasonable introduction to the group and its literature.

Radiolarians

Modern Ecology and Preservation

The term radiolarian refers to several closely related groups including Phaeodarians and Acantharians but only the polycystine radiolarians (with two primary divisions, Spumellaria and Nassellaria) form robust siliceous shells that fossilize well, and all paleontologic uses to date are of polycystines. Radiolarians are small (~40–400 µm) grazers of phytoplankton, bacteria, and exported organic detritus in the surface to deep water layers of all modern oceans. Radiolarian shells (Figure 1) show an amazing range of shapes and geometries, and can be quite elaborate. Ever since Haeckel first published his illustrations of radiolarians, they have attracted the interest of artists and designers. For scientists, the complex forms of radiolarian shells provide numerous morphologic characteristics for distinguishing species. There are approximately 400 known living species of polycystine radiolarians (WoRMS, 2010), most of which are also found as fossils in Quaternary sediments. Most species are restricted to specific habitats. Some are found only in polar regions, others only in tropical waters, while yet others are found only in deep water masses (Boltovskoy et al., 2010; Figure 2). Radiolarians, as is generally true of siliceous skeletons, are preserved in sediments only when the flux of opaline material into the surface sediment is relatively high and dilution within the sediment by other components is not

too strong. They generally are most common in ocean sediments where carbonate preservation is poor: polar regions, deep Indo-Pacific sediments along the equator, and ocean margin upwelling zones. In the modern ocean, radiolarian preservation patterns closely mirror that of the more abundant producers of opal – diatoms and both distributions are similar to that of surface ocean productivity (Figure 3). The presence of radiolarians is thus sometimes taken as an indicator of productivity, although this is more a secondary coincidence due to the linkage of preservation patterns to diatom productivity in surface waters.

Preparation Methods

Quaternary radiolarians (and silicoflagellates) are extracted from sediments using simple chemicals such as HCl and H₂O₂ to dissolve/disaggregate the sedimentary matrix, and sieving to obtain clean specimens. Smaller radiolarian species and larger silicoflagellates require 38 µm sieves, although this often causes significant dilution by diatom frustules in diatomaceous sediments. Larger mesh sieves, particularly 63 µm, are often used for biostratigraphic studies for this reason, but may not adequately recover many small forms important for ecologic analysis. Transmitted light microscopes with brightfield illumination and 100–400× total magnification are fully adequate for observation and counting purposes. SEM imaging rarely yields significant additional morphologic information and is primarily used for older (e.g., Mesozoic) faunas where recrystallization of opal to other minerals makes transmitted light observation difficult.

Applications

Water mass boundaries

The geographic distribution of most marine plankton closely reflects that of the water masses they live in and is also true of radiolarians, which show a strong latitudinal diversity gradient as well (Figure 4). Highly diverse faunas of radiolarians (up to 200 species) are found in the warm surface waters of the tropics and subtropics. Mid-latitude surface waters contain a lower diversity assemblage, partially of cosmopolitan forms, and partially of species characteristic of temperate regions. Distinctly different species are found in the lower diversity assemblages (50–100 species) of polar regions. Some of these polar species appear to be high-latitude cosmopolites, but others are found only in one or two of the three modern polar regions (North Pacific; Norwegian-Greenland Sea, and Southern Ocean) (Figure 2). Other species are primarily associated with subpolar fronts, or exclusively in low- to mid-latitude upwelling zones (Figure 2). This remarkably detailed faunal adaptation to surface water mass distributions is largely preserved in the fossil faunas found in underlying surface

Figure 1 Examples of radiolarian shells (a–d, Spumellaria; e–g, Nassellaria). (a) *Actinomma antarcticum*, (b) *Stylatractus universus*, (c) *Euchitonia* sp., (d) *Tetrapyle* sp., (e) *Cycladophora davisiana*, (f) *Ceratocyrtis histicosa*, (g) *Siphocampe arachnea*, and (h) *Theocorythium trachelium*.

Figure 2 Radiolarian biogeographic patterns. Darker shades indicate higher relative abundance within the whole radiolarian assemblages in surface sediments. The distributions of four species are shown. Most living radiolarian species can be classified as having one of these distribution patterns: tropical taxa (*Spongaster tetras*, a), subtropical (*Acrosphaera lappacea*, b), polar (*Antarctissa denticulata*, c), and frontal/gyre margin/upwelling (*Cycladophora davisiana*, d). Redrawn from Lombardi G and Boden G (1985) Modern radiolarian global distributions. Cushman Foundation for Foraminiferal Research, Special Publication, 16A.

sediments, despite changes in individual species' relative abundances due to preservation artifacts. Thus, the biogeography of fossil radiolarian faunas can be used to map out the history of ocean water mass geography, and, particularly in high latitudes, to a much finer resolution than is possible with calcareous microfossils, as these latter have very low diversities (generally only a few rather cosmopolitan taxa) in cool temperate to polar regions. A good Quaternary example of this method using radiolarians is [Morley \(1989\)](#).

Biostratigraphy

Although biostratigraphic applications of radiolarians are primarily in older sediments (indeed, most radiolarian workers are engaged in biostratigraphy of Mesozoic and Paleozoic rocks), radiolarians are also occasionally important as biostratigraphic markers in Quaternary sediments. Two important examples include the last occurrence of the spumellarian species *Stylatractus universus* and abundance fluctuations in the nassellarian species *Cycladophora davisiana*.

Figure 3 Radiolarian abundance in Atlantic Ocean surface sediments. Darker shades indicate higher absolute abundance of radiolarians (shells/gram sediment). The distribution primarily reflects opal preservation in sediments, due to the saturation of silica in sediment pore waters in opal-rich sediments. Opal abundance in sediments is primarily caused by high surface water productivity and the dominance in such waters of siliceous diatom phytoplankton. In regions without abundant opal production (e.g., oligotrophic central gyres) virtually all radiolarian skeletons eventually dissolve as modern sea water is very undersaturated in silica. Redrawn from Goll RM and Bjørklund KR (1971) Radiolaria in surface sediments of the North Atlantic. *Micropaleontology* 17(4): 434–454; Goll RM and Bjørklund KR (1974) Radiolaria in surface sediments of the South Atlantic. *Micropaleontology* 20(1): 38–75.

The last occurrence datum (LAD) of *Stylatractus universus* Hays 1970 (Figure 1) was first noted from the late Pleistocene in Antarctic sediments and subsequently noted in several other ocean basins, all in the late Pleistocene (see review in Hays and Shackleton, 1976). Hays and Shackleton (1976) calibrated the age of this event to the same interval in glacial–interglacial oxygen isotope curves in several widely distributed piston cores from the Indo-Pacific (stage 11/12 boundary; currently ca. 430 ka (Moore et al., 1995)). Morley and Shackleton (1978) subsequently extended this calibration with additional cores from the Atlantic Ocean. This datum is thus global (Figures 5 and 6) and has proved to be very useful in interpreting and cross-correlating oxygen isotope curves during the CLIMAP and SPECMAP projects, as the event conveniently falls approximately in the middle of the Brunhes magnetochron, thus providing a globally recognizable calibration point above the base of the Brunhes.

Of all radiolarian taxa used in Quaternary research, *Cycladophora davisiana* Ehrenberg 1862 (Figure 1) is perhaps the most important, being valuable both for biostratigraphic and paleoecologic studies. In addition to using this species as an

Figure 4 Radiolarian diversity versus latitude, showing faunal groups in relation to oceanographic fronts. The red curve shows the number of species found in each of a series of surface sediment samples taken in a transect from the western equatorial Pacific to the Southern Ocean southeast of New Zealand. The blue curve shows the Shannon–Wiener relative abundance weighted diversity metric calculated from the same samples. Patterns of covariation in abundance in the entire sample set were analyzed using a clustering algorithm to classify the samples into a small set of similar faunal groups. The boundaries between these groups, shown on the right side of the figure, closely match physical oceanographic boundaries that are crossed by the transect (labeled lines). Redrawn and replotted from Boltovskoy D (1987) Sedimentary record of radiolarian biogeography in the equatorial to Antarctic western Pacific Ocean. *Micropaleontology* 33(3): 267–281.

important indicator of glacial conditions, Hays et al. (1976a) in their seminal ‘pacemaker’ paper (which established the dominance of Milankovitch frequencies in Quaternary climate change) also noted the importance of *C. davisiana* to Quaternary stratigraphy. This was more explicitly studied by Morley and Hays (1979) who noted that this species increased dramatically in relative abundance in synchrony with oxygen isotope glacial–interglacial stages in North Atlantic cores. In a series of papers this was also established for most other ocean regions (see review in Brathauer et al., 2001). In modern oceans, this species is common only in the Sea of Okhotsk and in the centers of low to mid-latitude upwelling regions (Figure 2; Lombardi and Boden, 1985). Its increased abundance in glacial intervals (Figure 7) is thought to reflect changes in midwater ecology, as this species primarily inhabits the intermediate (subthermocline) layers in the Sea of Okhotsk today (Nimmergut and Abelman 2002).

Figure 5 *Stylatractus universus* LAD calibration core sites location map (based on data in Hays and Shackleton, 1976; Morley and Shackleton, 1978). The last occurrence of this species has been correlated to the same stage of the globally synchronous time scale of the Pleistocene oxygen isotope curve.

Figure 6 Isochroneity of the LAD *Stylatractus universus* as shown by comparison to oxygen isotope stratigraphy in two representative cores. Blue lines show abundance of *S. universus*; red lines the oxygen isotope composition of benthic foraminiferal shells in down-core sediment samples. The isotope curves are part of a longer time series of data from the cores which permit each cycle of the curve to be uniquely identified to the global reference standard isotope stages (top of each figure), and thus to absolute time. *S. universus* abundance declines to very low levels during the transition between isotope stages 12 and 11, and the species disappears completely within the early part of isotope stage 11. Redrawn from Morley JJ and Shackleton NL (1978) Extension of the radiolarian *Stylatractus universus* as a biostratigraphic datum to the Atlantic Ocean. *Geology* 6(5): 309–311.

Many other radiolarian biostratigraphic events are found in the Quaternary and are of at least regional importance. Summaries of biostratigraphic zonations for radiolarians in different geographic regions that include Quaternary events can be found in Sanfilippo et al. (1985).

It should be noted that most radiolarian biostratigraphic events are either only found within one biogeographic region, or if present in more than one region, may have slightly

different ages, or even show regular gradational variation in event age with geography (Moore et al., 1995). This is due to the very close adaptation of most radiolarian species to specific water masses and to environmental gradients within them. The high precision and global validity of the LAD of *S. universus* is exceptional and is most likely due to a preference for globally distributed deep water masses, although this can only be inferred for this now extinct form.

Figure 7 Covariation of *Cycladophora davisiana* and glacial-interglacial oxygen isotopes in down-core samples from a sub-Antarctic deep-sea sediment core. Blue line shows variation in relative abundance of *C. davisiana*, red line shows oxygen isotope composition of benthic foraminiferal shells (glacial intervals are indicated by more positive oxygen isotope values). *C. davisiana* is generally much more abundant during glacial intervals. *C. davisiana* abundance curves can be used in sediment cores lacking stable isotope data to identify glacial-interglacial time intervals. Reproduced from Brathauer U, Abelmann A, Gersonde R, Niebler H-S, and Fütterer DK (2001) Calibration of *Cycladophora davisiana* events versus oxygen isotope stratigraphy in the subantarctic Atlantic Ocean – A stratigraphic tool for carbonate-poor Quaternary sediments. *Marine Geology* 175: 167–181.

Paleotemperature estimation

One of the main contributions marine microfossils make to Quaternary studies is the estimation of past ocean water temperatures. Radiolarians have been one of the most important groups of fossils for such studies. The most important early paleotemperature estimates using radiolarians were those of CLIMAP, both in down-core studies such as Hays et al. (1976a) and in a series of regional studies mapping out the temperatures of the surface ocean during the Last Glacial Maximum, as summarized in Hays et al. (1976b) and Moore (1978, 1980). Radiolarians, with their relatively high diversity and insensitivity to carbonate dissolution, provided much of the temperature reconstructions for CLIMAP in high-latitude regions, as well as in deeper basins of the Pacific (CLIMAP, 1976).

Figure 8 Location of surface sediment samples used to create a radiolarian temperature transfer function for the sub-Antarctic to Antarctic South Atlantic. The relative abundances of species from these samples were analyzed using factor analysis to define four main groups of species that vary in geographic abundance in a uniform way. Reproduced from Lazarus DB (2005) A brief review of radiolarian research. *Paläontologische Zeitschrift* 79(1): 183–200; redrawn from Abelmann A, Brathauer U, Gersonde R, Sieger R, and Zielinski U (1999) Radiolarian-based transfer function for the estimation of sea surface temperatures in the Southern Ocean (Atlantic sector). *Paleoceanography* 14(3): 410–421.

Several more recent studies using similar methods have been published, including those of Heusser and Morley (1985) in the North Pacific and Dolven et al. (2002) in the Norwegian–Greenland Sea. These more recent studies have sometimes introduced methodological improvements over those of CLIMAP. Pisias et al. (1997), in a review of radiolarian paleotemperature equations for the Pacific, noted the problem of covariation in summer and winter temperatures, and instead created regression equations for mean annual water temperature and seasonality in water temperature, which are much less highly correlated to each other. Abelmann et al. (1999; Figures 8–10) in the Antarctic recognized differences in water depth habitat of different radiolarian species and those species known to live only in subsurface layers were excluded from the set of taxa used to estimate surface water temperatures. Cortese et al. (2005) used a neural network program instead of a multivariate statistical method to estimate paleotemperatures in Norwegian–Greenland sea sediments. However, despite these methodological improvements, the magnitude of error in paleotemperature estimation has improved only slightly, for example, to 1–2 °C, which is similar to that achieved for other microfossil groups. It is likely that this level of error represents limits due to other methodologic and ecologic problems, such as taxonomic error, and more importantly, limits on the extent to which radiolarian assemblage composition is actually controlled by water temperature.

Paleoproductivity estimation

Organisms in the real world are rarely adapted to and primarily responsive to only one major environmental parameter such

Figure 9 South Atlantic surface sediment radiolarian assemblage factor distributions (relative abundance in sediment samples; see [Figure 8](#)) versus modern surface ocean temperature. Each differently colored curve represents a distinct geographic radiolarian species assemblage (red, tropical/subtropical; yellow, subpolar, green, Polar Front; blue, Southern Ocean. Reproduced from Lazarus DB (2005) A brief review of radiolarian research. *Paläontologische Zeitschrift* 79(1): 183–200; redrawn from Abelmann A, Brathauer U, Gersonde R, Sieger R, and Zielinski U (1999) Radiolarian-based transfer function for the estimation of sea surface temperatures in the Southern Ocean (Atlantic sector). *Paleoceanography* 14(3): 410–421.

as temperature. This is certainly also true of radiolarians, although to what degree is generally unknown. This is, however, substantial indirect evidence that the distributions of radiolarians and other planktonic organisms are controlled at least

Figure 10 Correlation between actual ocean water temperature and water temperature estimated from radiolarian transfer function in South Atlantic. Estimated temperatures are from multiple regression of radiolarian factors defined in earlier steps ([Figures 8 and 9](#)). Reproduced from Lazarus DB (2005) A brief review of radiolarian research. *Paläontologische Zeitschrift* 79(1): 183–200; redrawn from Abelmann A, Brathauer U, Gersonde R, Sieger R, and Zielinski U (1999) Radiolarian-based transfer function for the estimation of sea surface temperatures in the Southern Ocean (Atlantic sector). *Paleoceanography* 14(3): 410–421.

as much by food availability as by any other factor. This was already apparent in the global distributional data collected for radiolarians from surface sediments by the CLIMAP project (summarized in [Lombardi and Boden, 1985](#); [Figure 2](#)), as well as in analyses of species distribution in the water column by [Casey et al. \(1982\)](#). Many species distributions do not match temperature distributions but instead are more closely aligned with frontal systems or follow large-scale patterns of primary productivity in the ocean. [Molina-Cruz \(1977, 1984\)](#) first explicitly attempted to apply the distribution of radiolarians to map ocean productivity. This effort was limited by CLIMAP's focus on temperature reconstruction, incomplete knowledge of radiolarian habitats in the water column, and by the limited data available at that time on ocean productivity distribution.

A second approach to this problem was developed by [Nigrini and Caulet \(1992\)](#), based on their observation of a recurrent pattern of unusual species distributions in association with low- to mid-latitude upwelling zones. They noted that certain radiolarian species are found, either exclusively or in unusual abundance, in widely separated upwelling regions, including the Somali system in the Indian Ocean and the Peru-Chile upwelling system in the Pacific. The relative summed abundance of these 'upwelling' species in the total radiolarian assemblage was used to define an upwelling radiolarian index, or URI. In subsequent papers Caulet and coworkers generated URI time series for several cores in late Pleistocene sediments, mostly from the Somali upwelling system, and compared to other inferred proxies of paleoproductivity such as planktonic foraminiferal faunas and $\delta^{13}\text{C}$. In general, URI curves show moderate to good correlation with other paleoproductivity

Figure 11 Variation over the last ca. 140 ka in the upwelling radiolarian index (URI) versus accumulation rate of carbonate in a tropical Indian Ocean core located above the calcium carbonate compensation depth (CCD). Because the core is situated above the CCD and has only minor nonbiogenic material, the bulk accumulation rate is used as a proxy for productivity. Replotted from data shown in [Caulet et al. \(1992\)](#).

proxies, although substantial differences are also often seen in certain time intervals ([Figure 11](#)). URI curves also occasionally show patterns that are difficult to interpret, or are at variance to other paleoceanographic proxies of productivity ([Jacot des Combes and Abelmann, 2007](#)). Use of the URI as a paleoproductivity proxy is, however, limited by many factors. These include a lack of knowledge of the underlying biologic controls on species distributions (what specifically causes these enhanced relative abundances within the upwelling zone), by the limited stratigraphic range of many of the species, several of which have so far only been reported from the Pleistocene, and by latitude. In higher latitudes, several of the species used are relatively common even outside of upwelling regions and thus not suitable as markers of upwelling activity.

[Jacot des Combes et al. \(1999\)](#) began the development of a third approach to estimating paleoproductivity, based on an early proposal by [Casey et al. \(1982\)](#), who had suggested that the relative abundance of deep-water dwelling species should be enhanced in areas of upwelling and/or enhanced export productivity. This would be due to both the cooling and

eutrophication of surface waters, which would depress the abundance of warm, oligotrophic adapted surface water taxa, and by the enhanced abundance of deeper water taxa, that, directly or indirectly, would be able to feed off the higher levels of exported organic matter to intermediate and deep water layers. Methods based on this ecologic principle were christened WADE methods (for WAter Depth Ecology) by [Lazarus \(2005\)](#). In [Jacot des Combes](#)' approach, the ratio in relative abundance between a small number of surface water and deep water taxa was employed as a thermocline–surface radiolarian index (TSRI), with higher relative abundances of deep-water taxa yielding higher TSRI values and an inferred higher level of export productivity. The TSRI index often correlates reasonably well with other productivity indicators, although down-core patterns of variation can be complex and shift over time ([Jacot des Combes et al., 2005](#)). The TSRI can also be applied in open ocean regions outside of upwelling regions, as demonstrated by [Jacot des Combes et al. \(1999\)](#). The TSRI, however, is limited by the small number of species used. Due to complex adaptation to multiple environmental constraints, individual species of radiolarians (and generally most organisms) are not

always common in regions or individual samples within their preferred biogeographic province, or even at 'optimum' conditions for any one environmental parameter. This variation in abundance can strongly bias indices, such as the TSRI, that are based on just a few taxa. Weinheimer (2001) and Lazarus et al. (2006, 2008) developed an extended version of the WADE

method by employing a much larger number of taxa (>50) to document both long-term trends and glacial–interglacial scale variation in radiolarian faunas within the Benguela upwelling system (Figure 12(a) and 12(b)).

WADE methods, due to their lack of dependence on specific taxa, can in principle be applied even to older sediments and

Figure 12 Radiolarian Water Depth Ecology (WADE) indices based on large numbers (>50) of surface and deep-water dwelling species, and their correlation to environmental change indicators in sediments from the Benguela Upwelling system off of Africa in the western South Atlantic. (a) Correlation of WADE index to total organic carbon content of sediments (TOC) over the last 6 million years in two deep-sea drilling sites: Site 1084 near the center of upwelling, and Site 532 near the edge. (b) WADE productivity index in samples covering the last few glacial–interglacial cycles from upwelling Site 1084. Samples are assigned estimated global benthic $\delta^{18}\text{O}$ values according to sample age as a proxy for degree of glacial–interglacial environment. Glacial samples have generally much higher productivity, as indicated by lower values of the WADE index. Reproduced from Lazarus D, Bittniok B, Diester-Haass L, Meyers P, and Billups K (2006) Comparison of radiolarian and sedimentologic paleoproductivity proxies in the latest Miocene–Recent Benguela Upwelling System. *Marine Micropaleontology* 60: 269–294; Lazarus D, Bittniok B, Diester-Haass L, et al. (2008) Radiolarian and sedimentologic paleoproductivity proxies in late Pleistocene sediments of the Benguela Upwelling System, ODP Site 1084. *Marine Micropaleontology* 68: 223–235.

with extinct taxa, so long as the water depth preferences of these forms can be independently established. WADE methods are also based on a clear ecologic model and thus the data should be relatively easy to interpret. However, the choice of which taxa to use is still rather arbitrary and the number of studies using these methods is still very small. Furthermore, neither URI nor WADE indices have yet been calibrated in surface sediment assemblages to independent measurements of ocean productivity. It is thus too early to make any general conclusions as to their robustness.

Outlook for the Use of Radiolarians in Quaternary Studies

Radiolarians, due to their wide-ranging ecology, robust opaline shell chemistry, and high diversity, provide an important record of Quaternary marine environments that complements that provided by other microfossil groups such as diatoms and planktonic Foraminifera. They provide paleotemperature estimates and estimates of paleoproductivity and provide useful biochronologic information as well. Importantly, radiolarians provide useful information from sediments lacking well preserved carbonate. Such sediments are common in environmentally critical areas of the ocean, for example, high latitudes and low-latitude upwelling zones. The limitations to the use of radiolarians are primarily our own. For example, the first reasonably comprehensive lists of living species names, and maps of living species distributions, both appeared only quite recently (Boltovskoy et al., 2010; WoRMS, 2010) and many of the entries in these syntheses are still quite sketchy. We still know far too little about living radiolarian ecology, particularly for individual species, and even the descriptive taxonomy of Quaternary radiolarians is incomplete. As our taxonomic and ecologic knowledge of the group improves, the importance of radiolarians in Quaternary research is likely to increase.

Silicoflagellates

Silicoflagellate skeletons are generally intermediate in size between diatoms and radiolarians (mostly 20–100 μm), and often co-occur on microscope slides prepared for examination of these other groups (Figure 13). They thus are occasionally studied by diatom and radiolarian workers, as well as by silicoflagellate specialists. Their living diversity is very low – just a few species – and moderately low diversity has been characteristic of the group since its origin in the Cretaceous. The silicoflagellate skeleton is composed of tubular elements connected into simple ring-like structures, external radial spines, plus a central apical structure in some taxa. The taxonomy of silicoflagellates is based on the number of sides of the geometric basal ring and the complexity of the apical structure. The small number of resulting morphologic characters may contribute to the low described diversity of taxa. However, recent work suggests that paleoceanographically significant subspecies level variation may be present within traditional species definitions, which can be exploited in future research (Malinverno, 2010). Silicoflagellates are normally found as only a minor component of biosiliceous sediments, and then only when silica is relatively well

Figure 13 Silicoflagellate skeletons (*Distephanus* sp.). Skeleton size, with spines, c.40 μm .

preserved. Their occurrence can thus be used as a rough indicator of overall good opal preservation state, but the preservation characteristics of silicoflagellates have never been studied in detail.

Silicoflagellates have been studied in the plankton for decades and numerous studies have reported both seasonal and geographic variations in relative taxa abundances, and in overall levels of absolute and relative flux, in comparison to other groups (see e.g., Onodera and Takahashi, 2005). Thus, in principle it should be possible to use fossil silicoflagellate occurrence patterns to study past environments, as is done for radiolarians. However, uncertainties in species-level taxonomy, low overall diversity, and sporadic occurrence in surface sediments have limited the development of normal paleoenvironmental tools such as transfer functions and paleoenvironmental analysis has remained primarily qualitative. However, the ratio between the two current living genera, *Dictyocha* and *Distephanus*, has sometimes been useful as a relative temperature indicator in paleoceanographic research (Barron et al., 2010; Figure 14).

There are one or two Quaternary biostratigraphic events reported for silicoflagellates (McCartney, 1995; Perch-Nielsen, 1985) but these have not been used much in biostratigraphic research.

Acknowledgments

The author thanks Kevin McCartney for useful comments on a draft of the silicoflagellate text, Reed Scherer for the initial suggestion to contribute, Elke Siebert for drafting Figures 2 and 3 and an anonymous reviewer for several important suggestions on how to improve the manuscript.

Temperature Proxies, Census Counts

J D Ortiz, Kent State University, Kent, OH, USA

© 2013 Elsevier B.V. All rights reserved.

Introduction

Because the historical sea-surface temperature (SST) record extends back only to the late 1800s, paleoceanographers must rely on indirect measures of temperature – referred to as temperature proxies – to reconstruct thermal fluctuations during most of the Quaternary and earlier geologic periods. An ideal temperature proxy would instantaneously record unbiased temperature changes in a way that was insensitive to postdepositional change. While all temperature proxies fall short of this ideal, a number of approaches are sufficiently robust to provide quantitative results. Here we discuss quantitative methods that assume that the biogeography of marine microorganisms is controlled either by temperature or a correlated environmental variable such as thermocline structure or nutrient content. The statistical methods described below employ census counts of microfossils of marine fauna and flora and have been used to reconstruct conditions at the surface or in the deep sea. Planktonic Foraminifera are widely distributed in the world's oceans. Temperature reconstructions using the shells of these organisms capture the global range of temperature variability and biogeographic provinces within the ocean (e.g., cool eastern margins, warm gyres, cold polar regions, etc.). In modern usage, four types of multivariate methods are used: coiling ratios of *Neoglobquadrina pachyderma*, transfer functions employing Q-mode factor models, modern analog methods, and neural networks. Coiling ratios of *N. pachyderma* are applied only in the high latitudes where taxonomic diversity of the planktonic Foraminifera tends toward a single morphotype or taxon. The latter methods, which can be applied throughout the world's ocean, are relatively unbiased, and capable of precision that ranges from ± 0.8 to ± 1.5 °C.

Ecological Basis

Theory

Their simple physiology, great abundance, relatively short lifespan, and planktonic habit make microorganisms one of the best choices among marine organisms as the basis for quantitative reconstruction of marine properties such as surface temperature and productivity. While marine microfossils are extremely useful due to their widespread distribution, they cannot provide high resolution geochemical time series with subannual resolution such as those that can be extracted from corals, sclerosponges, or mollusks (see [Oxygen-Isotope Stratigraphy of the Oceans](#)). The distribution of a marine microorganism is controlled by its ecological niche, the sum total of the environmental factors that affect the organism during its lifespan. Organisms reach maximum abundance within their optimal niche zone and decrease in abundance away from this optimum. A common misconception regarding microfossil-based paleotemperature proxy methods is that the fundamental assumption upon which they are based that the distribution

of the organisms studied is controlled solely by temperature. While it is certainly true that temperature plays a very important role in the distribution of marine microorganisms, it is not the sole factor determining their distribution. Rather, factors such as food availability, thermocline structure, nutrient levels, competition, and predation help to shape the ecological success, and thus biogeographic distribution of these organisms. These competing factors place a theoretical lower limit on the precision that can be achieved using these methods.

This truth was not lost on [Imbrie and Kipp \(1971\)](#) who proposed a regression-based approach to reconstructing paleoceanographic temperature change using statistically transformed planktonic foraminiferal assemblages. This transfer function approach has come to be known as the Imbrie–Kipp method (IKM). They recognized that the biogeography of simple microorganisms is controlled by a suite of correlated environmental variables. Because surface temperature in the modern ocean is highly correlated with other temperatures within the euphotic zone and with most other near-surface environmental fields, they reasoned that the reconstruction of sea surface temperatures is well justified. The fundamental assumption behind these statistical methods is thus best stated as follows: the biogeography of simple microorganisms is controlled either by temperature or a correlated environmental variable. As a corollary, the relationship between the organism and its environment must not change during the interval of paleoceanographic reconstruction. The task at hand thus becomes determining a means by which to scale the observed variability in the foraminiferal data to yield robust estimates of paleoceanographic changes in temperature or some other environmental variable. There is, of course, a limit to the number of environmental variables that can conceivably be reconstructed in this way. While temperature is the most commonly reconstructed parameter, paleoproductivity has been reconstructed with success (e.g., [Mix, 1989a,b](#)) because on global scales, temperature and production are uncorrelated. Traditionally, warm and cold season temperatures have been reconstructed (e.g., [CLIMAP, 1976, 1981](#)), with the rationale that different organisms live during different times of the year and thus impart independent information on the fossil record. This is a largely pragmatic decision, as seasonal reconstruction is desirable. This particular approach has been criticized because monthly and seasonal temperatures are so very highly correlated due to the strength of the seasonal cycle. [Mix \(1989a,b\)](#), proposed a novel solution to this problem by reconstructing mean annual temperature and annual temperature range, two environmental variables that are essentially uncorrelated.

Validity of Assumptions

The validity of the fundamental assumptions has been tested in a number of ways. The most common approach is to argue that the

assumptions are valid because a statistically significant relationship can be generated between a single environmental field such as temperature and core-top foraminiferal faunal data. This is not an entirely satisfying argument because the least squares methods which are often applied in these approaches must yield positive, definite results and thus any additional variables added to a statistical model must increase the amount of variance explained. More direct approaches to testing the hypothesis include comparison of statistical methods using different families of microorganisms (e.g., Foraminifera vs. radiolarian) or against geochemical paleotemperature proxy methods. In many cases, the results may disagree primarily because the proxies may be responding to different variables, seasons, or depth habitats. Because of this, perhaps the most stringent test of the fundamental assumptions arises from experimental culture work on planktonic Foraminifera (e.g., [Bijma et al., 1990](#)), and field observations of planktonic foraminifer using plankton tows (e.g., [Bé and Hutson, 1977](#)) or sediment traps (e.g., [Mohiuddin et al., 2005](#); [Thunell and Reynolds, 1984](#)), or studies that combined plankton tow, sediment trap, and core top data ([Wilke et al., 2009](#)). [Ortiz and Mix \(1997\)](#), for example, compared the effectiveness of the IKM against the traditional modern analog method, using both sediment trap and core top calibration data sets. Their work indicated that the modern analog technique (MAT) produced global temperature estimates with smaller residuals and that the sediment trap faunas produced reliable temperature estimates when the core top methods were applied to them.

As an alternative, [Morey et al. \(2005\)](#), using canonical correspondence analysis (CCA), found support for these assumptions by demonstrating that core top foraminiferal assemblages from the Atlantic and Pacific Oceans were correlated with two CCA axes. The primary axis was controlled by surface temperature, while the secondary axis was inversely correlated with temperature and positively correlated with a suite of environmental variables related to productivity. They also found no statistically significant overprint of dissolution recorded in the foraminiferal faunas, suggesting that post-depositional changes may not be as severe a problem as has often been assumed. [Žarić et al. \(2005\)](#) came to similar conclusions regarding the relative importance of temperature and production on the flux and relative abundance of planktonic foraminiferal populations collected from 42 sediment traps distributed through the world's oceans. This generalization may not hold on all regional scales; however, [Siccha et al. \(2009\)](#) found that in the warm waters of the Red Sea, productivity seemed to be the dominant factor controlling glacial-interglacial variations of foraminiferal faunas potentially because the low latitude position of this environment minimizes the range of observed SST variation.

Other studies have explored the impact of seasonality on paleotemperature estimation. [Salguero et al. \(2008\)](#), employing core top faunas from the Iberian Margin, found that the variety of paleotemperature methods discussed here tended to underestimate SST in southern regions with intermittent upwelling and overestimate SST in the north where colder waters are present year round. [Fraile et al. \(2009\)](#) modeled fluxes of foraminiferal species to document how seasonally shifting temperatures can alter the seasonal flux patterns and thus influence foraminiferal faunal paleotemperature estimates.

Approaches

Statistically Significant Census Counts and Percent Abundance Data

A number of approaches have been proposed to estimate paleotemperature using microfossil data. The microfossil shells or tests of organisms that once lived in the water column settle to the sea floor and are incorporated into the sedimentary record in great abundance. Although the distribution of these organisms varies as a function of time, water depth, and location, there may be thousands to tens of thousands of foraminiferal tests per cubic gram of sediment. These microfossils are extracted from the sediment and sorted into taxonomic groups. The number of recent morphotypic foraminiferal taxa recognized by various authors range from around 26 to as many as 45. The discrepancy arises from variations in regional faunal abundance and differences in opinion regarding taxonomic distinctions.

The great abundance of these organisms in the sediment means that only a subsample of the total population is usually analyzed. A basic question that must be addressed then is the number of individual shells that should be analyzed to produce statistically meaningful results. Traditionally, 300–350 individuals from all taxa are counted ([Imbrie and Kipp, 1971](#)), a value which is selected as a balance between accuracy and effort. [Dryden \(1931\)](#), working with mineral grains, presented a probability relationship and figures through which this 'rule' can be understood:

$$p_e(\text{in shells}) = 0.6745 \times \sqrt{(np(1-p))}$$

where p_e is the probable error, n =total number of shells counted, and p =fractional abundance of the taxa in question. While Dryden's work was conducted with mineral grains, it applies equally well to microfossil data. Because the error function follows a square root, p_e must fall off asymptotically as n increases. The turning point in the function lies between 50 and 100 shells. Thus the cost, in terms of the number of shells that must be identified to minimize a given error, grows disproportionately relative to the resulting improvement in accuracy. Using calculations from [Dryden \(1931\)](#), when $p=0.5$, to obtain a 1% accuracy would require counting 4549 total shells, while a 5% accuracy would require only 200! Because the error increases with decreasing p (i.e., as taxa become rare), a value of $n \approx 300$ was selected as a reasonable compromise between accuracy and analytical efficiency. The errors associated with counting this number of total shells range from around 17% error for a taxon with 5% abundance down to about 2.5% error for a taxon with 80% abundance. Increasing the count to around 750 total shells decreases this range only to 11% error for the rare species, and about 1.5% for the abundant species. Therefore, counting as many as 1000 shells per sample represents significant effort for only modest returns.

Morphotypes Versus Genotypes

The relative percentages of the organisms in the fossil assemblage record environmental information that can be extracted through a variety of quantitative means, once they have been sorted into morphotypes or taxa defined based on phenotypic

traits observable in the foraminiferal shell. In general, these morphotypes have specific geographic distributions and are often referred to in the literature as 'species.' Recently, however, this assumption has been tested through the application of genetic techniques to assess the level of genetic variability within the Foraminifera. The first important result to arise from this work is that rates of genetic drift within the Foraminifera are consistent with the molecular clock hypothesis, implying that rates of speciation within the Foraminifera should be sufficiently slow to certify their reliability as climate recorders on evolutionarily short timescales such as the Quaternary. Perhaps more importantly, these studies have enabled the development of genotypically defined foraminiferal species for the first time. The results of this work have been striking. To date, 33 cryptic genetic types have been found in 9 of the 22 sequenced morphotypes that have been studied (Kucera and Darling, 2002). These genetic types have specific geographic ranges. When an estimate of the modern geographic distribution of these cryptic genotypes was incorporated into core top

temperature reconstructions using the range of multivariate methods discussed below, the results improved the predicted temperature estimates by 5–34% (Kucera and Darling, 2002). Unfortunately, we currently cannot apply this approach to the fossil record, as it is as yet not possible to differentiate these genetic morphotypes on the basis of observed phenotypic variation (Kucera and Darling, 2002).

Classes of Microfossil-Based Paleotemperature Proxy Methods

In general, the worker seeks to determine a quantitative relationship between a foraminiferal response and environmental forcing (Figure 1) using a calibration data set based on faunas generally extracted from core tops (e.g., Mix et al., 1999; Prell et al., 1999) and environmental data from an oceanographic atlas (e.g., WOA, 1998). The relationship developed using this training or calibration data set is then applied to downcore data to infer past environmental conditions.

Figure 1 Latitudinal transects of SST estimates in the Atlantic comparing SST reconstructions by artificial neural network (ANN), similarity maximum method (SIMMAX) and revised analog method (RAM). Gray shaded area envelops modern SST values (WOA, 1998) at the same stations, (a) Northern summer; (b) austral summer; (c) annual average. Enlarged symbols mark severe no-analog samples excluded from triangulation. Error estimates for each method average on the order of 1 °C. Reprinted from Kucera M, Weinelt M, Kiefer T, et al. (2005b) Reconstruction of sea-surface temperatures from assemblages of planktonic foraminifera: Multi-technique approach based on geographically constrained calibration data sets and its application to glacial Atlantic and Pacific Oceans. *Quaternary Science Reviews* 24: 951–998.

Table 1 Overview of the MARGO planktonic foraminifer data sets with prediction errors for individual regions

Calibration data set				Root mean square error of prediction (°C)					LGM data set	
Region	Source	Samples	Remarks	SST	ANN	RAM	SIMMAX	MAT	Cores	Samples
North Atlantic	1	862		Summer	1.14	1.09	0.91	1.42	102	550
				Winter	0.96	0.79	0.86	1.32		
				Annual	0.96	0.85	0.81	1.26		
South Atlantic	1	321	83 tropical samples in common with North Atlantic	Summer	0.81	0.76	0.98	1.36	69	198
				Winter	0.95	0.96	0.98	1.47		
				Annual	0.83	0.62	0.93	1.36		
Pacific	1	1111	Some core tops common to IndoPacific data set 13 LGM cores common to IndoPacific data set	Summer	1.19	0.78	1.00	1.63	82	265
				Winter	1.64	1.17	1.27	1.88		
				Annual	1.35	0.93	1.10	1.67

				Winter	0.79	0.47				
				Annual	0.91	0.54				
Indian Ocean and Australia (IndoPacific total)	3	1344	Some core tops common to Pacific data set 13 LGM cores common to Pacific data set	Summer	0.93	0.91		0.89	170	301
				Winter	1.01	1.98		1.98		
				Annual	0.86	0.86		0.84		
									460	1574

The error rates have been determined by cross validation of the calibration data sets using ten independent partitions (artificial neural network (ANN) and modern analog technique (MAT) and revised analog method (RAM) for Indian Ocean and Australia) and the leaving-one-out method (similarity maximum method (SIMMAX), RAM, MAT). MAT values for North and South Atlantic and Pacific data sets refer to error rates for SIMMAX without distance weighting. Note that the leaving-one-out procedure in RAM02 software, used for all regions except the Indian Ocean and Australia underestimates the error rate as the samples are 'left out' after the two-dimensional interpolation procedure.

Sources for tabulated results: Kucera et al., (2005b); Hayes et al., (2005); Barrows and Juggins (2005). Reprinted from Kucera M, Weinelt M, Kiefer T, et al. (2005b) Reconstruction of sea-surface temperatures from assemblages of planktonic foraminifera: Multi-technique approach based on geographically constrained calibration data sets and its application to glacial Atlantic and Pacific Oceans. *Quaternary Science Reviews* 24: 951–998.

One approach to this problem is to generate a multiple linear regression between surface temperature and the raw percent abundance of the taxa found in the sediments (e.g., Vincent and Berger, 1981). This approach proved to be less than satisfactory due to instability of the regression coefficients as a result of intercorrelation of the input foraminiferal data. This problem, sometimes referred to as 'multicollinearity' results in an overfitted regression model that may produce plausible regression statistics during the initial modern calibration phase, but which yields unrealistic downcore proxy temperature estimates. That is to say that multiple taxa of Foraminifera may respond to correlated environmental information in one way in the modern environment and in a different way in the past. Therefore, when the interaction between the environmental forcing changes downcore, the regression will no longer yields valid results.

In modern usage, four types of methods are employed: coiling ratios of *N. pachyderma*, transfer functions employing Q-mode factor models (the IKM), modern analog methods, and neural networks. Coiling ratios of *N. pachyderma* are applied only in the high latitudes where taxonomic diversity of the planktonic Foraminifera tends toward a single morphotype or taxon. The latter methods, which can be applied throughout the world's oceans, are relatively unbiased, and capable of precision that ranges from ± 0.8 to ± 1.5 °C (Figure 1, Table 1). At high latitudes, the multivariate methods perform poorly. This is evident in Figure 1 as a systematic bias in

paleotemperature estimates in the North Atlantic. As pointed out in Kucera et al. (2005b), each of these multivariate methods has difficulty reproducing temperatures in cold high-latitude regions where faunal diversity decreases rapidly toward assemblages dominated by a single morphotype, *N. pachyderma* (s.).

Imbrie–Kipp Transfer Function Method

The IKM was proposed as the means of solving the multicollinearity problem (Imbrie and Kipp, 1971). The method employs Q-mode factor analysis to simplify a large matrix of variables measured on many samples. Q-mode factor analysis is often used when many variables are measured at multiple spatial or temporal points. The Q-mode method seeks to preserve the 'information' within the samples of the data set, rather than the variance within the variables. We use the term 'information' rather than variance because each sample represents a set of measurements on many variables that may differ greatly in their variance. Fundamentally, a data matrix ($\mathbf{U}_{ct}$) is decomposed into a factor score matrix ($\mathbf{B}_{ct}$), a factor loading matrix ($\mathbf{F}_{ct}$), and an error matrix ($\mathbf{E}_{ct}$):

$$\mathbf{U}_{ct} = \mathbf{B}_{ct}\mathbf{F}_{ct} + \mathbf{E}_{ct}$$

The factor score matrix represents linear combinations of the original foraminiferal census count data (factors

assemblages) that are combined in such a way that they are independent of each other, or orthogonal. The rows in the factor loading matrix indicate the relative contribution of each factor assemblage to each sample in the data set. This approach effectively deals with the intercorrelation between the input variables, allowing stable regression parameters to be determined from stepwise multiple linear regression of the factor loading matrix against the environmental data. This was the basis of the CLIMAP temperature reconstructions and became a standard procedure for estimation of environmental information from a variety of microfossil groups. [Ortiz and Mix \(1997\)](#) report that this method can produce errors on the order of $\pm 1.9^\circ\text{C}$ when employed with a global calibration data set.

Modern Analog Methods: MAT, SIMMAX, RAM

Until recently, the principle alternative to the IKM was the modern analog method ([Prell, 1985](#)). This approach remains in many ways closer to the original microfossil census data than the IKM. The basic assumptions behind the modern analog methods are that similar foraminiferal faunas are produced by similar environmental conditions, and as in the IKM, that temperature either controls or is correlated with the environmental factors that give rise to the foraminiferal assemblages. The task of the investigator is thus to employ some index with which to compare multidimensional foraminiferal assemblage data to determine which are most similar (or least distinct). A variety of metrics or dissimilarity indices have been proposed and these form the basis for differentiating between the three primary variants of the modern analog method that have developed.

The traditional MAT as applied by [Prell \(1985\)](#) made use of the squared chord distance, defined as:

$$d_{ij} = \sum \left[p_{ik}^{1/2} - p_{jk}^{1/2} \right]^2$$

where the sum is calculated over all taxa recognized, and p_{ik} and p_{jk} represent the percentages of taxa k , in two samples i and j . Samples with unknown environmental conditions are compared against a calibration data set to find the best analogs. Environmental conditions at the locations of the best analogs are then averaged as specified by the user to estimate the paleoclimate conditions under which the assemblage from the unknown sample were likely generated. Advantages of this approach are that in general analysis of the environmental data is independent of the selection of the best analogs. The quality of the analogs obtained from the calibration data set can be assessed using the mean and standard deviation of the dissimilarity index and by the standard deviation of the environmental data obtained from the locations of the best analogs. This final consideration is important as it can be used to assess the uniqueness of the relationship between a particular fauna and the environment. However, a primary consideration in the application of the method is that the results are strongly dependent on the quality of the calibration data set. Larger and more environmentally comprehensive calibration data sets yield more reliable results. [Ortiz and Mix \(1997\)](#) reported that this method can produce errors to the order of $\pm 1.5^\circ\text{C}$ when employed with a global calibration data set consisting of

1121 samples. Two variants of the modern analog method have been developed. These are referred to as the similarity maximum method (SIMMAX) and revised analog method (RAM) methods. Both of these methods exhibit precision to the order of ± 0.8 to 1.0°C , but these improved error estimates may underestimate the true error in the methods for reasons described below ([Table 1](#)).

The SIMMAX method (e.g., [Pflaumann et al., 1996](#)) differs from the traditional MAT method by using the scalar product of the normalized faunal assemblages as the similarity index, and then weighting the contribution of the best analogs obtained by the inverse of their distance from the location where the sample for paleotemperature reconstruction was obtained. This latter condition places a strong constraint on the resulting paleotemperature reconstruction, effectively nudging the solution back toward the modern environmental field. [Kucera et al. \(2005a,b\)](#) report an average SIMMAX error of $\pm 0.98^\circ\text{C}$ and an average MAT error of $\pm 1.3^\circ\text{C}$, but the latter was determined using the SIMMAX method without its distance-weighting function, a standard way of applying the method ([Table 1](#)). [Kucera et al. \(2005a,b\)](#) state that this is identical to the classical MAT method but is not strictly correct since SIMMAX and the traditional MAT of [Prell \(1985\)](#) do not use the same dissimilarity index.

The RAM merges the traditional MAT with the response surface method, which is a standard procedure in palynology ([Waelbroeck et al., 1998](#)). This method seeks to describe the faunal or floral distribution as a simultaneous function of two or more environmental variables (i.e., to map out an environmental response surface). These variables could be warm and cold season temperature or annual temperature and productivity, for example. The first step in the RAM process is to interpolate the foraminiferal and environmental fields to a fixed grid specified by the user. The gridding procedure enables the faunal composition to be estimated for all combinations of the input environmental fields in the data set. This, of course, requires that the data sets be sufficiently well distributed to yield reliable results. Following this step, the traditional MAT method of [Prell \(1985\)](#) is applied to the interpolated fields with the modification that the number of best analogs retained is determined based on the derivative of the calculated dissimilarity coefficients using a user-determined threshold ([Kucera et al., 2005b](#)). The RAM method is capable of errors to the order of $\pm 0.8^\circ\text{C}$, but this error is perhaps an underestimate, since the errors are calculated on the basis of the interpolated fields and not the ungridded data ([Table 1](#)).

Artificial Neural Networks

The implementation of artificial neural networks (ANNs) as a tool to infer paleotemperature using foraminiferal census data ([Malmgren and Nordlund, 1997](#)) represents a significant departure from the statistical approaches employed, and has the potential to be the most significant advance in the field in recent decades. The ANN method differs significantly from previous methods in that sets of interconnected processing units (neurons) explore the relationship between the input census data and the environmental field(s) believed to force the foraminiferal response. The network then uses an

optimization procedure to minimize the errors in prediction of the environmental variable in relation to the observed foraminiferal faunas. The learning process is completed when additional information no longer minimizes the prediction error. A subset of samples is reserved for validation of the resulting network. The advantages of this approach are that properly trained ANNs are less dependent on the size of the calibration data set than other methods such as the MAT, and the method is capable of extrapolating to conditions outside of the initial environmental data set (Kucera et al., 2005b). The primary disadvantages of the approach are that the ANN solution obtained from a pairing of foraminiferal census data and environmental data is not unique, the method is computationally expensive, and it can be difficult to determine the underlying relationship between the foraminiferal census data and the environmental forcing. The lack of a unique solution is addressed by averaging the results from multiple ANN solutions. Considerable caution must be exercised when establishing the initial conditions under which the method is applied (e.g., number of neurons employed, fraction of data held in reserve, and number of networks developed for comparison). Despite these potential difficulties, Kucera et al., 2005b demonstrate that the method is capable of producing results with an average precision of $\pm 1.0^\circ\text{C}$ (Table 1).

Selected Case Studies

Planktonic foraminiferal faunal temperature estimates were initially developed for use with late Quaternary faunas. Over the span of several thousand years, it was argued that the evolution of these taxa – and thus potential changes in their relationship to the environment due to genetic drift – were minimal. Qualitative methods, such as changes in the relative proportion of tropical versus subtropical taxa, or quantitative application of transfer function methods are now being applied over a much broader range of geologic time. At one extreme, workers are applying these methods in environments with extremely high sedimentation rates to study variation on multidecadal to centennial timescales. In contrast, others are employing these approaches to infer changes in paleotemperature millions of years ago. Staines-Urías et al. (2009) used a combination of foraminiferal faunas and geochemical proxies to study multidecadal and centennial variations in SST and thermocline structure in the Gulf of California. Kandiano and Bauch (2007) argued that marine isotope stage (MIS) 11 may not serve as a good analog for future Holocene climate because faunal, geochemical, and lithologic data suggested that the early evolution of water masses during MIS 11 differed significantly from that of the early Holocene. Schaefer et al. (2005) studied the evolution of the Subtropical Front east of New Zealand over the past 1 Ma. Sato et al. (2008) compared variations in planktonic foraminiferal faunas with oxygen isotopes and Mg/Ca derived from planktonic Foraminifera to determine that the modern Western Pacific Warm Pool was established during the Pliocene by 3.6 Ma, in response to the constriction of the Indonesian seaway and the closure of the Central American seaway. Perhaps the most ambitious effort to expand the use of planktonic foraminiferal faunal SST estimates is the Pliocene Research, Interpretation and Synoptic Mapping

Project, which is combining planktonic foraminiferal faunal estimates with alkenone and Mg/Ca temperature estimates to construct boundary conditions to force coupled ocean atmosphere general circulation models to simulate ocean circulation during the Pliocene, a potential analog for future warming (Dowsett and Robinson, 2009; Dowsett et al., 2009). Their results suggest that the pronounced warmth of the Pliocene was driven by a combination of enhanced greenhouse forcing and meridional heat transport (Dowsett et al., 2010).

Controversies

Microfossil-based paleotemperature proxy methods have been employed in numerous studies since their inception, largely as part of the CLIMAP project. The results of these studies have significantly advanced our understanding of climate change on a variety of timescales, but not without controversy. Perhaps the two most significant problems associated with this class of methods are the generic no-analog problem, and the specific warm Last Glacial Maximum (LGM) tropics problem.

All of the methods described above are sensitive – to some degree – to the no-analog problem. This is effectively a violation of the assumption that the response of the foraminiferal faunas to climate is invariant between the calibration faunas and the downcore faunas of interest. In extreme cases, no-analog conditions can result from excessive environmental stress (e.g., mass extinction events), which can modify foraminiferal assemblages and morphology (Keller and Abramovich, 2009). The no-analog problem is generally manifest through poor goodness-of-fit statistics, such as communality with respect to the IKM, or large dissimilarity functions with respect to the modern analog methods. Because it postulates a specific statistical relationship between the foraminiferal faunas and the environmental response, the IKM is more sensitive to no-analog problems than the various modern analog approaches, provided that they employ sufficiently large calibration data sets.

Perhaps the greatest controversy associated with microfossil-based paleotemperature proxy methods is the warm glacial tropics problem. A surprising result of the CLIMAP reconstruction was the prediction that the tropics either did not cool significantly or may have warmed to the order of 1°C in some regions. These results did not agree with theoretical estimates, modeling studies, or geochemical estimates that predicted changes as great as $5\text{--}6^\circ\text{C}$ in some places. This seemingly implausible result has spawned numerous studies using a variety of techniques. Revised geochemical work now infers tropical glacial cooling to the order of 3°C with considerable spatial heterogeneity.

Mix et al. (1999) presented another interesting approach toward dealing with the no-analog problem in the Atlantic basin. Rather than using a core top calibration data set, they generated downcore factors, then projected these factors onto core top faunas, which formed the basis for an Imbrie–Kipp paleotemperature calibration. When the paleotemperature calibration was used to scale the observed downcore factor pattern, significant cooling, to the order of $2\text{--}3^\circ\text{C}$ was observed, particularly in eastern boundary current regions. Similarly, Barrows and Juggins (2005) using the MAT, RAM, and ANN methods observed glacial cooling to the order of 4°C in the

Indian Ocean, while Kucera et al. (2005b) observed glacial cooling of $>3^{\circ}\text{C}$ in the eastern equatorial Pacific and eastern boundary currents using the ANN, RAM, and SIMMAX with and without distance scaling. Chen et al. (2005) employed the IKM, MAT, SIMMAX, RAM, and ANN methods in a study of glacial temperatures in the western Pacific. Their results indicate that while the MAT, SIMMAX, RAM, and ANN methods all predicted temperatures $\sim 1^{\circ}\text{C}$ cooler, the IKM method (which performed poorly in the calibration process) inferred no glacial temperature change relative to modern. Steinke et al. (2008) compared five different faunal transfer function methods and found nearly unchanged or unusually high paleotemperatures in the South China Sea during the Last Glacial Maximum. These results were in contrast to the $2\text{--}5^{\circ}\text{C}$ cooling observed with U^{k}_{37} and Mg/Ca geochemical methods. They concluded that the anomalously warm paleotemperatures derived from the foraminiferal faunal methods were the result of a no-analog fauna in the glacial interval, which exhibited abundances of *N. pachyderma* (dex.) and *P. obiquiloculata* greater than their abundance in the core top calibration data set. Li et al. (2009) proposed use of a morphometric paleotemperature index based on the test size of *O. universa* in the South China Sea as a means of addressing this particular no-analog faunal problem.

While sampling issues may have contributed to the warm glacial tropics problem, the majority of the thermal discrepancy appears to have arisen from a no-analog problem and the use of the traditional IKM, which is most sensitive to this problem. One approach toward addressing this problem is to base results on the comparison of a variety of methods when generating microfossil-based paleotemperature estimates (e.g., Chen et al., 2005; Hayes et al., 2005; Kucera et al., 2005a,b; Nyberg et al., 2002). This approach is consistent with the ‘no free lunch’ theorem from the field of machine learning, which states that no single statistical method can provide optimal classification or prediction results with all data types, although some methods may perform better with specific data sets than others. A promising study along these lines was provided by Assareh et al. (2010). They compared a series of machine-learning algorithms to evaluate their relative potential in paleotemperature estimation. They employed a Monte Carlo method consisting of a genetic algorithm (GA) that compared the performance of 1000 different classifier teams in four classes (IKM, MAT, regression trees, and ANNs) over 500 randomized iterations. The GA randomized the input parameters of the predictors in the classifier team, retaining the best classifiers and discarding the poorly performing classifiers at each iteration step. In this way, the classifier team ‘evolves’ over the course of the Monte Carlo iterations. The resulting paleotemperature classifier team produced errors to the order of $\pm 0.88^{\circ}\text{C}$ and was dominated by the ANN team members.

Introduction

Observations from Antarctic ice cores have revealed a tight correlation between temperature and atmospheric pCO_2 over the past 800 ka, with glacial periods displaying $\sim 30\%$ lower pCO_2 compared to interglacials. Although the temperature– pCO_2 covariation strongly suggests CO_2 may be an important amplifier of climate change, ice cores do not reveal the causal mechanisms of the glacial–interglacial CO_2 variations.

The ocean is the only reservoir capable of absorbing the amount of carbon needed to explain the lowering of atmospheric pCO_2 from interglacial to glacial levels. Due to the larger land ice extent during glacial periods, the terrestrial biosphere must have been smaller and thus acted as a source of CO_2 to the atmosphere, rather than a sink. Because CO_2 does not only physically dissolve in seawater but chemically reacts with it to form carbonic acid and bicarbonate and carbonate ions, the ocean contains ~ 50 times more carbon than the atmosphere. The 30% decrease in glacial atmospheric pCO_2 and terrestrial biosphere reduction therefore translate into a mere $1\text{--}2\%$ increase in the marine carbon inventory, demonstrating how a small change in the ocean inventory can cause dramatic changes in the atmospheric inventory. Knowledge of the origin and amplitude of past fluxes between carbon reservoirs is therefore important for evaluating the role of CO_2 in climate forcing.

Marine carbonate chemistry can be described by six parameters: aqueous PCO_2 , HCO_3^- , and CO_3^{2-} concentrations, the sum of all dissolved carbon species in the ocean

($\text{DIC} = [\text{CO}_2] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}]$), alkalinity, and seawater pH. Because these parameters are governed by equilibrium reactions, knowledge of any two of these parameters, in addition to temperature, salinity, and pressure, allows for calculation of the entire marine carbonate system. In contrast to inclusions of ancient air in glacier ice, an archive for pristine seawater does not exist for the past and carbonate parameters cannot be measured directly. Paleocceanographers therefore use proxies, that is, measurable quantities that hold a close relationship to the desired parameter but which are preserved in the geological archive. These are often chemical and isotopic compositions of the fossil remains of organisms, as well as physical descriptors such as grain sizes, shell weights, and microstructures. Water pressure can be approximated by the preferred depth habitat of the organism in consideration; we focus here on proxies describing specific parameters of the marine carbonate system. Tools available to date are the boron isotopic composition ($\delta^{11}\text{B}$) of marine carbonates as a proxy for seawater pH, trace metal to calcium ratios of B, U, Cd, Zn, and Ba, as well as foraminiferal shell weights and stable carbon isotopes ($\delta^{13}\text{C}$) for reconstructing the amount of dissolved carbon, and $\delta^{13}\text{C}$ of alkenones as a proxy for aqueous PCO_2 .

Carbon Cycle Proxies

The Boron Isotope Proxy for Seawater pH

The basis for the boron isotope–pH proxy has been described in detail by [Hemming and Hanson \(1992\)](#). Briefly, there are

Figure 1 (a) Distribution of the two dominant boron species dissolved in seawater, boric acid ($B(OH)_3$) and borate ($B(OH)_4^-$), versus pH. The equilibrium constant, pK_B , was determined by Dickson (1990). (b) Boron isotopic composition of aqueous boron species versus seawater pH, calculated from the fractionation factor of Klochko et al. (2006). The dashed line indicates $\delta^{11}B$ of seawater, which is constant at $\sim 39.6\text{‰}$. Modern marine carbonates record an isotopic composition that falls close to the isotopic composition of dissolved borate in seawater (Hemming and Hanson, 1992).

Figure 2 Empirical relationships between $\delta^{11}B$ and experimental seawater pH measured in five species of corals, two species of planktic foraminifers, and inorganically precipitated calcite. Although all carbonate calibration curves fall close to the isotopic composition of dissolved borate in seawater (dashed black line), there are significant offsets between them and they consistently describe a shallower slope than suggested by the aqueous fractionation. Paleoreconstructions therefore need to be restricted to monospecific carbonates that are calibrated for the $\delta^{11}B$ /pH relationship.

two dominant species of dissolved boron in the ocean, boric acid [$B(OH)_3$] and borate [$B(OH)_4^-$], and their relative concentration changes with pH. At low pH (<7) boron exists in the form of $B(OH)_3$, whereas at high pH (>10) boron occurs predominately in the form of $B(OH)_4^-$ (Figure 1(a)). There are also two isotopes of boron, ^{10}B and ^{11}B , and because of differences in vibrational energy and molecular geometry, $B(OH)_3$ is enriched in ^{11}B relative to $B(OH)_4^-$, with a measured isotope fractionation of $\sim 27\text{‰}$ between the two boron species

(Klochko et al., 2006). Consequently, as the relative concentration of the dissolved species changes with pH, so does their isotopic composition (Figure 1(b)).

$\delta^{11}B$ of planktic foraminifers, corals, and inorganically precipitated $CaCO_3$ fall close to the boron isotopic composition of $B(OH)_4^-$ over a wide range of seawater pH (Figure 2). However, all empirical calibration curves describe a $\delta^{11}B$ -pH relationship with a shallower slope than the one measured for aqueous boron isotope fractionation. To reflect the difference between the larger aqueous fractionation of $\epsilon \sim 27\text{‰}$ and the smaller value that best describes the carbonates, we distinguish the use of an empirical value for the boron isotope fractionation into marine carbonates as $\epsilon^* \sim 20\text{‰}$. To translate the $\delta^{11}B$ of fossil carbonates into paleo-pH values, the following equation can be used:

$$pH = pK_B - \log \left(\frac{-(\delta^{11}B_{\text{seawater}} - \delta^{11}B_{\text{carbonate}} - a)}{(\delta^{11}B_{\text{seawater}} - \alpha^* \times (\delta^{11}B_{\text{carbonate}} + a) - \epsilon^*)} \right)$$

where pK_B is the equilibrium constant for the boric acid/borate system, $\delta^{11}B_{\text{seawater}}$ in the modern ocean is 39.6‰ , fractionation $\epsilon^* = (\text{carbonate fractionation factor } \alpha^* - 1) \times 1000$, and a is the constant offset between the apparent aqueous borate and empirical $\delta^{11}B$ -pH-calibration curve for a specific calcium carbonate. Because offsets between different calcifiers are significant (Figure 2), it is important to restrict paleoreconstructions to single species that are calibrated for the $\delta^{11}B$ /pH relationship.

It has also been shown that physiological processes such as respiration, calcification, and symbiont photosynthesis change pH in the microenvironment of a calcifying organism. Culture experiments with living, symbiont-bearing foraminifers have revealed a higher $\delta^{11}B$ of specimens grown in the light relative to individuals grown in the dark (Hönisch et al., 2003). Because the empirical carbonate calibrations shown in Figure 2 are largely parallel to each other despite the different nature of calibrated organisms and their respective calcification schemes,

Figure 3 Comparison of atmospheric $p\text{CO}_2$ measured in ice cores (gray line) and surface ocean PCO_2 reconstructed from boron isotopes in shells of the planktic foraminifers *G. ruber* (Seki et al., 2010) and *G. sacculifer* (Hönisch et al., 2009) and ϵ_p in alkenones (Seki et al., 2010). The width of the PCO_2 band from the alkenone reconstruction indicates the PCO_2 -uncertainty based on assumed high (lower boundary) and very high (upper boundary) phosphate availability to alkenone-producing coccolithophores. The average PCO_2 uncertainty of boron isotope reconstructions for the Pleistocene is $\sim 20 \mu\text{atm}$. PCO_2 values from oligotrophic ocean regions, where modern aqueous PCO_2 is in equilibrium with atmospheric $p\text{CO}_2$, generally match atmospheric $p\text{CO}_2$ within the analytical uncertainty of the reconstruction. However, alkenone PCO_2 estimates heavily rely on nutrient estimates, and reconstructions using the same global calibration do not always match atmospheric $p\text{CO}_2$ (cf. Figure 9). Sample selection for boron isotope and alkenone reconstruction by Seki et al. (2010) is believed to be biased toward interglacial periods.

Figure 4 In some species of planktic foraminifers, B/Ca exhibits relationships with pH and/or temperature (a and b). The empirical partition coefficient, K_D , also varies with temperature (d), though the relationship is not consistent across species. The K_D -temperature correlation is positive for *G. inflata* and *G. bulloides*, and negative for *G. ruber* and *G. sacculifer*. It is not yet clear whether this indicates a species-specific effect or whether different relationships are observed because of the influence of an unidentified environmental control. All data shown are derived from modern marine sediments. B/Ca from cultured *O. universa* increases with pH (a), but does not exhibit a strong relationship with temperature (b).

it appears that vital effects due to physiological processes are constant over a wide range of seawater pH and thus do not generally compromise the use of the boron isotope proxy. However, analyses of different shell size classes of the symbiont-bearing foraminifer *Globigerinoides sacculifer* have revealed an increase of $\delta^{11}\text{B}$ with shell size (Hönisch and Hemming, 2004; Ni et al., 2007). This pattern could be explained by larger individuals spending relatively more time closer to the sea surface, where light levels are higher and the effect of symbiont photosynthesis on $\delta^{11}\text{B}$ is larger (Hönisch and Hemming, 2004). Because $\delta^{11}\text{B}$ is also affected by dissolution and the dissolution effect is smallest in the largest shells, it is preferable to use large shells in a narrow size range for paleoreconstructions (Hönisch and Hemming, 2004).

Despite these potential complications, Hönisch and Hemming (2005) and Foster (2008) have demonstrated that quantitative reconstruction of ancient seawater pH and atmospheric $p\text{CO}_2$ is feasible if sample selection and data analysis are done carefully (Figure 3). However, beyond the past 3–5 million years, paleoreconstructions are hampered by uncertainties regarding $\delta^{11}\text{B}_{\text{seawater}}$. Until paleoceanographers find a way to better constrain the value of $\delta^{11}\text{B}_{\text{seawater}}$ through time, reconstructions of the distant past are restricted to relative changes across a climate event rather than absolute pH values.

The B/Ca Proxy for Surface Seawater pH and Bottom Water Carbonate Saturation

The ratio of boron to calcium in foraminiferal calcite (B/Ca) is influenced by seawater carbonate chemistry, with a theoretical

basis similar to that of boron isotopes. Borate ($\text{B}(\text{OH})_4^-$) is more abundant in seawater at higher pH, and if $\text{B}(\text{OH})_4^-$ is the species predominantly incorporated into calcite (as boron isotopes suggest), then B/Ca should increase with pH. Planktic foraminifers from coretop sediments (Foster, 2008; Yu et al., 2007) do indeed exhibit B/Ca relationships with environmental parameters such as pH and temperature (Figure 4(a) and 4(b)). However, because many parameters tend to covary in surface seawater (e.g., temperature, salinity, alkalinity), it has been difficult to distinguish specific control(s) on B/Ca from coretop samples.

To isolate the influence of single variables on B/Ca in planktic foraminifers, culture experiments have been performed with *Orbulina universa* under tightly controlled laboratory conditions (Allen et al., 2011). In these experiments, B/Ca increases with pH, salinity, and seawater boron concentration, but not with temperature. Because raising pH of seawater concurrently affects $[\text{CO}_3^{2-}]$, $[\text{HCO}_3^-]$, and alkalinity, the *O. universa* data cannot be used to discern the

direct influence of these different parameters on B/Ca. Efforts to tease apart and quantify their respective influences on B/Ca are currently in progress. The effect of salinity ($2.6 \mu\text{mol mol}^{-1}$ per salinity unit in *O. universa*) does not pose a large complication for glacial–interglacial timescale reconstructions when salinity changes are small, but will need to be considered for larger changes such as occurred earlier in Earth history.

To constrain the carbonate system in past surface seawater, some researchers have applied calibrations with an empirical boron partition coefficient (K_D , defined as $[\text{B/Ca}]_{\text{carbonate}}/[\text{B}(\text{OH})_4^-/\text{HCO}_3^-]_{\text{seawater}}$). Determination of K_D in this manner is based on the assumption that $\text{B}(\text{OH})_4^-$ and HCO_3^- are the dominant aqueous species incorporated into calcite, and that $\text{B}(\text{OH})_4^-$ substitutes into the CO_3^{2-} lattice site. Modern K_D calibrations have been established by combining coretop B/Ca with modern surface-ocean hydrographic data (Figure 4(d); Foster, 2008; Yu et al., 2007). However, paleoreconstructions utilizing K_D calibrations must be treated with caution until the carbonate system controls on B/Ca are better understood and quantified. We do not know whether borate and bicarbonate are truly the only species relevant to B incorporation, so K_D may not accurately represent B partitioning into calcite. In addition, temperature effects are not consistent between studies and are not observed in culture experiments (Figures 3 and 4(c)), so temperature-dependent K_D calibrations may need to be reconsidered.

In benthic foraminifers, B/Ca does not appear to be directly controlled by seawater pH, but instead increases with carbonate saturation or ΔCO_3^{2-} . Both the absolute B/Ca value and the slope of the B/Ca– ΔCO_3^{2-} relationship vary by species

Figure 5 In benthic foraminifers, B/Ca increases with bottom water ΔCO_3^{2-} . Different species are characterized by different B/Ca concentrations, ranging across an order of magnitude from $\sim 25 \mu\text{mol mol}^{-1}$ (*Uvigerina* spp.) to $\sim 250 \mu\text{mol mol}^{-1}$ (*C. wuellerstorfi*). The large B/Ca differences between species and their variable B/Ca – ΔCO_3^{2-} slopes suggest at least a partial biological control on B incorporation into benthic foraminiferal calcite. Reprinted from Yu J and Elderfield H (2007) Benthic foraminiferal B/Ca ratios reflect deep water carbonate saturation state. *Earth and Planetary Science Letters* 258: 73–86.

Figure 6 Empirical relationships between U/Ca in shells of *O. universa* and *G. bulloides* and seawater $[\text{CO}_3^{2-}]$. Foraminifers were grown under controlled conditions in the laboratory. The shaded area indicates the range of $[\text{CO}_3^{2-}]$ in modern surface seawater. Reprinted from Russell AD, Hönisch B, Spero HJ, and Lea DW (2004) Effects of changes in seawater carbonate ion concentration and temperature on shell U/Ca, Mg/Ca, and Sr/Ca of planktonic foraminifera. *Geochimica et Cosmochimica Acta* 68(21): 4347–4361.

(Figure 5), which indicates at least a partial biological control on B incorporation. The mechanism for the observed B/Ca– ΔCO_3^{2-} linkage is unclear, but application to glacial North Atlantic sediments gives water-column ΔCO_3^{2-} values that are consistent with $\delta^{13}\text{C}$ (Yu and Elderfield, 2007). The consistency of benthic B/Ca with water mass tracers and with other carbonate system proxies such as $\delta^{11}\text{B}$ suggest that B/Ca may serve as a valuable constraint on deep water chemistry in future studies.

U/Ca to Infer $[\text{CO}_3^{2-}]$

An early study by Russell et al. (1994) investigated the potential of foraminiferal U/Ca for reconstructing the seawater uranium inventory, which is a function of river inflow and removal into sediments overlain by anoxic bottom waters. Using culture experiments with living planktic and benthic foraminifers, the authors demonstrated that U/Ca ratio is incorporated proportional to the seawater concentration and thus may be a useful proxy. However, studying U/Ca from planktic foraminifers through geological time, Russell et al. (1996) found glacial U/Ca ratios approximately 25% lower than Holocene values. Such a large change could not be explained by changes in the seawater uranium concentration and Russell et al. (1996) therefore suggested the observed glacial–interglacial change may be predominantly controlled by seawater $[\text{CO}_3^{2-}]$ or temperature. This hypothesis has been confirmed in culture experiments with the living planktic foraminifers *O. universa* and *Globigerina bulloides*, which showed that while temperature does not exert a significant influence on uranium incorporation, foraminiferal U/Ca is inversely related to $[\text{CO}_3^{2-}]$ (Figure 6; Russell et al., 2004):

$$\text{U/Ca}_{O.universa} = 15.5 \exp(-0.0025[\text{CO}_3^{2-}])$$

$$\text{U/Ca}_{G.bulloides} = 27.9 \exp(-0.0025[\text{CO}_3^{2-}])$$

From a mechanistic point of view, the marine chemistry of uranium is linked to $[\text{CO}_3^{2-}]$ in two ways: (1) uranium occurs in seawater predominantly in the form of carbonate complexes and the concentration of the prevalent triscarbonate complex ($\text{UO}_2(\text{CO}_3)_3^{4-}$) decreases with pH, and (2) uranium adsorption onto shell surfaces is inhibited by $[\text{CO}_3^{2-}]$ (Russell et al., 2004, and references therein). Both mechanisms are consistent with the observation of decreasing U/Ca in foraminifer shells secreted under higher pH (or $[\text{CO}_3^{2-}]$).

Application of the experimental U/Ca relationship to equatorial Atlantic and Caribbean cores suggests glacial surface ocean $[\text{CO}_3^{2-}]$ was $80\text{--}110 \pm 60 \mu\text{mol kg}^{-1}$ higher than during the Holocene (Russell et al., 2004), an estimate that is similar to reconstructions using $\delta^{11}\text{B}$ or the deconvolution of the carbonate ion effect (CIE) on planktic foraminiferal carbon isotopes.

Although first applications demonstrate the proxy is generally promising, the study of several sediment cores revealed that contamination by authigenic carbonate formation may place a significant diagenetic overprint on the incorporated U/Ca. This may limit the general applicability of U/Ca to sediments above the redox front. Another diagenetic complication often observed in chemical proxies is the susceptibility

Figure 7 Zn partition coefficients (D_{Zn}) in *Cibicides wuellerstorfi* versus seawater ΔCO_3^{2-} . Measurements are from Holocene core tops from the North Atlantic (white), South Atlantic (dark gray), and Indo-Pacific (black). Line shows relationship used for converting D_{Zn} into ΔCO_3^{2-} (below $30 \mu\text{mol kg}^{-1}$) with 95% confidence intervals (dashed). Also shown is the original relationship proposed by Marchitto et al. (2000) (gray band). Reprinted from Marchitto TM, Lynch-Stieglitz J, and Hemming SR (2005) Deep Pacific CaCO_3 compensation and glacial–interglacial atmospheric CO_2 . *Earth and Planetary Science Letters* 231: 317–336.

of U/Ca to dissolution, which appears to decrease the original ratio (Russell et al., 1994).

Zn/Ca in Benthic Foraminifers

Marchitto et al. (2000) have shown that the partitioning of Zn (D_{Zn}) in tests of the benthic foraminifer species *Cibicides wuellerstorfi* and *Uvigerina* spp. reflects the concentration of dissolved zinc in bottom waters according to the following equation:

$$D_{\text{Zn}} = (\text{Zn/Ca})_{\text{foram}} / (\text{Zn/Ca})_{\text{seawater}}$$

However, Zn/Ca is also strongly affected by the saturation state of bottom waters during calcite precipitation such that D_{Zn} decreases with decreasing seawater calcite saturation state (ΔCO_3^{2-}). Although it has been suggested that these empirical data could represent reduced incorporation of trace metals in undersaturated waters during foraminiferal growth and/or preferential loss of Zn during postdepositional dissolution, investigations using Rose Bengal stained (i.e., recently living) foraminifer tests have shown that Zn/Ca incorporation is dominated by the effects of calcification rather than dissolution (Marchitto et al., 2000). As such, if ancient seawater zinc concentrations can be constrained, then foraminiferal Zn/Ca can be used to infer ΔCO_3^{2-} at the time of calcification.

In contrast to U/Ca and B/Ca, which are sensitive to seawater carbonate chemistry over a wide range of conditions, D_{Zn} is only sensitive to ΔCO_3^{2-} at $\Delta\text{CO}_3^{2-} < 30 \mu\text{mol kg}^{-1}$, that is, close to the saturation horizon in the deep ocean. Assuming a

linear relationship below $\sim 30 \mu\text{mol kg}^{-1} \Delta\text{CO}_3^{2-}$, the association between D_{Zn} and changes in carbonate ion saturation can be described by the following equation (Figure 7, Marchitto et al., 2005):

$$D_{\text{Zn}} = 0.143 \times \Delta\text{CO}_3^{2-} + 5.63$$

Application of this relationship to benthic foraminifers from sediments in the deep tropical Pacific allowed Marchitto et al. (2005) to infer deep ocean paleo- ΔCO_3^{2-} from the last glacial to the modern. Their data show glacial ΔCO_3^{2-} slightly lower than in the modern ocean as well as a brief positive excursion of $\sim 25\text{--}30 \mu\text{mol kg}^{-1}$ during the deglaciation. These data are broadly consistent with the hypothesis that the glacial addition of atmospheric CO_2 to the deep ocean caused dissolution of sedimentary CaCO_3 . During the deglaciation, CO_2 returned to the atmosphere, leaving the deep ocean temporarily oversaturated with respect to CaCO_3 , until deposition increased and a new equilibrium was subsequently established during the Holocene.

This study is a promising first attempt at using benthic foraminiferal Zn/Ca, but it has not yet been complemented by newer studies. Of particular concern for deeper time paleoreconstructions is the relatively short residence of Zn in the ocean, which is on the order of $\sim 10\text{--}30$ ka (Marchitto et al., 2005). In addition, Zn behaves like a nutrient and its deep ocean concentration varies as a function of organic matter degradation, making direct comparisons between different locations difficult in the absence of additional constraints. Further studies are needed to verify these initial results and in particular the Zn inventory of the paleocean should be better constrained.

Foraminiferal Ba/Ca

The distribution of dissolved barium in the modern ocean varies with alkalinity and silica in that all three are partially depleted in the surface ocean and more concentrated with increasing water depth. The removal of alkalinity, silica, and barium from surface waters is attributed to biological processes in which planktic calcifiers, diatoms, and radiolaria secrete CaCO_3 and opal skeletons, and barite (BaSO_4) is precipitated in association with decaying organic matter. Lea and Boyle (1989) pointed out that Ba and alkalinity are ocean-wide more closely related than Ba and silica, and although stoichiometric analysis of sinking particles and their regeneration in the deep sea could not fully resolve the mechanistic linkage between alkalinity and Ba (Lea, 1993), Lea (1993) suggested that changes in thermohaline circulation should still redistribute barium and alkalinity similarly, thereby allowing reconstruction of past alkalinity distributions from benthic foraminiferal Ba/Ca (e.g., Hall and Chan, 2004; Lea, 1993; Lea and Boyle, 1989).

In order for this proxy to faithfully record seawater alkalinity, the incorporation of barium in foraminiferal tests must be in proportion to the seawater Ba concentration, which has been verified in laboratory culture with planktic foraminifers. In addition, Ba incorporation furthermore does not appear to vary with temperature, salinity, or seawater pH (Hönisch et al., 2011, and references therein). However, benthic flux measurements in the modern Pacific and Atlantic Oceans found that

the Ba/alkalinity flux ratio was only $\sim 1/3$ of that expected from the modern deep-water trend, suggesting that the locations of precipitation and regeneration are not linked closely (Rubin et al., 2003). This may be an indication that the oceanic Ba-alkalinity correlation is not coupled on longer time scales and because the residence time of barium is relatively short (~ 10 ka), the accuracy of benthic foraminiferal Ba/Ca as an indicator of paleo-alkalinity remains in doubt.

Deconvolution of the CIE to Infer $[\text{CO}_3^{2-}]$

The stable isotopic composition of dissolved inorganic carbon in seawater ($\delta^{13}\text{C}_{\text{DIC}}$) is affected by a number of different processes, including global carbon cycling, ocean circulation, primary productivity, and organic carbon degradation. The carbon isotopic composition of marine carbonates ($\delta^{13}\text{C}_c$) records changes in $\delta^{13}\text{C}_{\text{DIC}}$, although carbon incorporation into the skeleton is also affected by additional parameters such as physiological life processes, shell size of planktic foraminifers and growth temperature. In addition, culture experiments with living planktic foraminifers have revealed that $\delta^{13}\text{C}_c$ and $\delta^{18}\text{O}_c$ decrease with increasing carbonate ion concentration and pH of the culture water (Spero et al., 1999, and references therein).

Mechanistic explanations for this CIE point to isotope fractionation between the dissolved carbon species in seawater. With regard to $\delta^{18}\text{O}_c$, the observed effect was attributed to the isotope partitioning between $[\text{HCO}_3^-]$ and $[\text{CO}_3^{2-}]$ in seawater and the relatively enhanced availability of isotopically lighter CO_3^{2-} at high pH (Zeebe, 1999). The effect on $\delta^{13}\text{C}_c$ is less well understood but may be related to physiological life processes, particularly respiration. Because at high pH the amount of respired CO_2 in the vicinity of a foraminifer is extremely high relative to ambient seawater concentration, Zeebe et al. (1999) suggested that conversion of this isotopically light CO_2 to HCO_3^- and CO_3^{2-} leads to an isotopic depletion of these carbon species relative to bulk seawater and thus to low shell $\delta^{13}\text{C}_c$.

Although these influences on foraminiferal $\delta^{13}\text{C}_c$ and $\delta^{18}\text{O}_c$ are relatively small, there is good evidence that marine carbonate chemistry measurably affects paleoceanographic records. For instance, the pH effect on foraminiferal $\delta^{18}\text{O}_c$ may be responsible for an underestimation of Cretaceous tropical sea surface temperatures (Zeebe, 2001), and instead of reporting the transfer of organic carbon from the terrestrial to the oceanic biosphere, the glacial-interglacial shift in $\delta^{13}\text{C}_c$ may be explained by higher glacial $[\text{CO}_3^{2-}]$ (Spero et al., 1997). Correcting $\delta^{13}\text{C}_c$ and $\delta^{18}\text{O}_c$ records for the CIE is therefore important for accurate paleoceanographic interpretations.

In addition, species-specific differences in the CIE also present a new way of reconstructing $[\text{CO}_3^{2-}]$ in the paleocean. Among the tested planktic foraminifers, *G. sacculifer* and *G. ruber* share approximately the same depth habitat, but the $\delta^{13}\text{C}_c/[\text{CO}_3^{2-}]$ slope (m) is twice as large in *G. ruber* as in *G. sacculifer* ($m_{G. \text{ ruber}} = -0.0089\text{‰} \mu\text{mol}^{-1} \text{ kg}$ and $m_{G. \text{ sacculifer}} = -0.0047\text{‰} \mu\text{mol}^{-1} \text{ kg}$). Assuming specific vital effects and depth habitat of these species did not change through time, the species-specific difference in the slopes can be used to distinguish between the effect of $[\text{CO}_3^{2-}]$ and a simultaneous change in $\delta^{13}\text{C}_{\text{DIC}}$ (for a detailed explanation see Spero et al., 1999). Application to the sediment record yields

Figure 8 Conceptual model of the $\delta^{13}\text{C}_{\text{alkenones}}$ proxy for seawater PCO_2 . The left panel shows a schematic phytoplankton cell with a membrane that is permeable for CO_2 to diffuse in and out of the cell. ϵ_p denotes the total photosynthetic carbon isotope fractionation between $\delta^{13}\text{C}$ of the carbon source in seawater and the organic product. ϵ_f reflects carbon fractionation associated with the enzymatic carbon fixation. μ is the growth rate and b is an empirical factor combining the effects of all physiological influences. The right panel visualizes the respective effects of CO_2 and μ on ϵ_p , where lower CO_2 and higher growth rate (shown in green) decrease ϵ_p , whereas higher CO_2 and lower growth rate (shown in blue) increase ϵ_p . Figures provided by courtesy of A. Benthien.

an estimate of $+55 \pm 63 \mu\text{mol kg}^{-1}$ in $[\text{CO}_3^{2-}]$ for the equatorial Indian Ocean during the last glacial period (Spero et al., 1999). Unfortunately, this method is restricted to tropical surface waters, where *G. sacculifer* and *G. ruber* both occur.

Carbon Isotope Fractionation in Alkenones to Infer Aqueous PCO_2

Alkenones are specific biomolecules that are exclusively synthesized by a group of calcite-secreting phytoplankton, coccolithophores. Alkenones are well preserved in marine sediments and their carbon isotope composition ($\delta^{13}\text{C}_{\text{alkenones}}$) has been used to reconstruct the aqueous concentration of CO_2 , $[\text{CO}_{2\text{aq}}]$, in the surface ocean. Reconstructing $[\text{CO}_{2\text{aq}}]$ from $\delta^{13}\text{C}_{\text{alkenones}}$ is based on the idea that marine phytoplankton assimilate CO_2 by passive diffusion from seawater into the cell, and the carbon isotope fractionation associated with the carbon fluxes in (F_{in}) and out (F_{out}) of the cell thus would be mostly controlled by $[\text{CO}_{2\text{aq}}]$. However, laboratory and field experiments have shown that photosynthetic carbon isotope fractionation (ϵ_p) can be influenced by a number of parameters, including nutrient concentration, irradiance, growth rate, and the carbon source, that is, CO_2 and/or HCO_3^- . Changing ideas of how photosynthetic carbon fractionation actually takes place is expressed by the different models used to describe the processes involved (Figure 8):

$$\epsilon_p = \epsilon_f - b/\text{CO}_2 \quad (1)$$

$$\epsilon_p = \epsilon_f - \mu/\text{CO}_2 \quad (2)$$

$$\epsilon_p = \epsilon_f \times F_{\text{out}}/F_{\text{in}} \quad (3)$$

where ϵ_f denotes the fractionation associated with enzymatic carbon fixation (e.g., 29‰ for the enzyme Rubisco), b is an empirical factor combining the effects of physiological influences, μ is the growth rate, and the term $F_{\text{out}}/F_{\text{in}}$ denotes CO_2 leakage, that is, the ratio of CO_2 efflux over influx. ϵ_p is thus small when growth rate is high and increases under elevated

$[\text{CO}_{2\text{aq}}]$, that is, when CO_2 leakage out of the cell increases (Figure 8). Traditionally, measured values of ϵ_p are shown versus $1/[\text{CO}_{2\text{aq}}]$ and if the equations described above are correct and ϵ_p was predominantly controlled by $[\text{CO}_{2\text{aq}}]$, alkenones should show a negative correlation between ϵ_p and $1/[\text{CO}_{2\text{aq}}]$. However, alkenones taken from core-top sediments in the South Atlantic display a positive correlation between ϵ_p and $1/[\text{CO}_{2\text{aq}}]$, indicating the dominant importance of nitrate and phosphate availability for the carbon isotope fractionation (Benthien et al., 2002). In addition, mesocosm culture experiments show that the isotopic fractionation varies by only 3–4‰ over a PCO_2 range from 180 to 700 ppmv (Benthien et al., 2007), demonstrating that the CO_2 sensitivity of $\epsilon_{\text{alkenones}}$ is low in the modern ocean, where coccolithophores are adapted to low $[\text{CO}_{2\text{aq}}]$. Despite these apparent complications, recent reconstructions of the Pliocene pCO_2 history from alkenones (Figure 9; Pagani et al., 2010) and boron isotopes and alkenones (Figure 3; Seki et al., 2010) have given promisingly similar estimates of Pliocene pCO_2 that are ~ 100 ppm higher compared to preindustrial times. In addition, early Cenozoic alkenone estimates are high and consistent with independent evidence for a warmer climate at that time (Pagani et al., 2005). It is clear from these studies that reasonable assumptions regarding nutrient concentrations have to be made to enable meaningful CO_2 estimates from alkenones. However, the comparison of reconstructions from six different sediment cores from the Atlantic and Pacific Ocean with atmospheric pCO_2 measured in ice cores (Figure 9; Pagani et al., 2010) demonstrates that a global $\delta^{13}\text{C}_{\text{alkenones}}$ calibration is insufficient to accurately describe different oceanographic settings (Figure 9).

Size-Normalized Shell Weights

The average shell weight of planktic foraminifers is primarily determined by their size, but there are measurable secondary relationships of shell mass to (1) ambient $[\text{CO}_3^{2-}]$ during shell precipitation (Barker and Elderfield, 2002), and (2) bottom water carbonate saturation, which drives shell dissolution

Figure 9 Plio-Pleistocene surface-ocean PCO_2 estimated from six different sediment cores in the Atlantic and Pacific Ocean. The map shows the core sites with their modern annual average phosphate concentrations ($\mu\text{mol l}^{-1}$), plotted from the World Ocean Atlas 2005 data set in Ocean Data View v. 4.0.1). The width of the data bands reflects maximum and minimum PCO_2 estimates as a function of nutrient concentrations at different alkenone production depths. Ice core pCO_2 is shown for comparison with each alkenone estimate and demonstrates that few alkenone estimates match atmospheric pCO_2 in coeval intervals. In contrast to the expectation that surface-ocean PCO_2 should be in equilibrium with atmospheric pCO_2 in oligotrophic ocean areas (sites 806 and 925, in purple), alkenone estimates best match ice core measurements in the mesotrophic–eutrophic North Atlantic (site 982, in blue). It is promising that all sites consistently show higher PCO_2 during the Pliocene but it is also obvious that single-site reconstructions may not yield reliable atmospheric pCO_2 estimates. Adapted from Pagani M, Liu Z, LaRiviere J, and Ravelo AC (2010) High Earth-system climate sensitivity determined from Pliocene carbon dioxide concentrations. *Nature Geoscience* 3: 27–30.

(Lohmann, 1995). To better constrain the small weight changes associated with these processes and to correct for size variability, paleoceanographers restrict their examinations to defined, narrow size ranges of single foraminifer species and collect a minimum of 50 shells per sample. Data from such samples are referred to as size-normalized shell weights (SNW), which can then be compared to similar samples of different age or location.

Because $[\text{CO}_3^{2-}]$ in both surface and deep waters changes through geological time, one needs to differentiate between variations in surface ocean calcification and deep ocean dissolution on a given sample, Barker et al. (2004) introduced a new approach where proximal sediment cores from depth profiles are compared. The shallowest cores are supposedly unaffected by dissolution and thus reflect shell weight changes through differences in $[\text{CO}_3^{2-}]$ during calcification in the surface ocean

only. This information can then be used to extract the effect of bottom water carbonate saturation on SNW changes in deeper cores.

Estimating changes in seawater $[\text{CO}_3^{2-}]$ from SNW of planktic foraminifers requires empirically calibrated relationships. Due to partial dissolution, the shell weight of nearly all species is lower in deeper water than it is in shallow water, and the decrease is continuous over a wide range of carbonate saturation states, even well above the calcite lysocline. Based on shell weights of three different planktic foraminifer species, Broecker and Clark (2001) determined an average weight-loss slope of $0.3 \pm 0.05 \mu\text{g } \mu\text{mol}^{-1} \text{kg}^{-1}$ decrease in pressure-corrected deep-sea carbonate ion concentration. This slope is provided as an example and should not be considered universal. Because susceptibility to dissolution differs between foraminifer species, species-specific relationships have to be applied to enable meaningful paleoceanographic reconstructions. Similarly, the SNW/ $[\text{CO}_3^{2-}]$ relationship in the surface ocean differs between species and also requires specific calibrations (Barker et al., 2004). In addition to specific calibrations, first studies indicate that additional factors such as growth habitat, food supply, salinity etc. need to be considered as potential secondary influences on the initial shell weight variability (Barker et al., 2004; Broecker and Clark, 2001). Although the relationship thus seems to be more complex than originally thought, application to the glacial north Atlantic resulted in realistic surface ocean PCO_2 estimates and $[\text{CO}_3^{2-}] \sim 60 \mu\text{mol kg}^{-1}$ higher than Holocene values (Barker and Elderfield, 2002).

To use SNW as a paleocarbonate ion proxy in ocean bottom water, this method requires the offset between pore and bottom water saturation to be constant. However, this may not be a valid assumption because calcite dissolution also occurs above the saturation horizon, where it is attributed to pore-water acidification caused by degradation of organic matter. The amount of organic matter reaching the seafloor varies between sites and also depends on depth. Assuming increased productivity during glacial intervals, the magnitude of this effect might have been even stronger. Application of this proxy should therefore be restricted to locations where strong changes in paleoproductivity are not expected.

Conclusions

Quantifying past changes in the amount and distribution of dissolved carbon in the ocean can clarify the role of CO_2 in climate change, and this may be accomplished by careful application of a variety of proxies for the marine carbonate system. The proxies described above are based on a wide range of independent organic and inorganic controls and are characterized by different strengths and weaknesses. The record of a target parameter may be compromised or limited by secondary influences of competing physical or chemical parameters, vital effects, diagenesis, limited availability of carbonates in the sedimentary archive, and temporal limitations via the residence time of an element in seawater. To improve confidence in paleoceanographic reconstructions of marine carbonate chemistry, comparison of various proxy data sets is therefore desirable. The general advantage of preservational proxies such

as shell weights is their non-destructive character, as weight analysis leaves foraminiferal samples untouched and allows further chemical investigation. Apart from providing additional information on carbonate saturation, knowledge of the foraminiferal preservation state can also elucidate the possible influence of dissolution on chemical proxies like $\delta^{11}\text{B}$ and U/Ca. Due to extensive culture studies with living planktic foraminifers, physical and chemical proxies are often better understood in planktic than in benthic foraminifers. This will probably change in the near future because recent progress in culturing benthic foraminifers promises the establishment of empirical proxy relationships under controlled laboratory conditions and better understanding of benthic proxies.

Acknowledgments

The authors would like to thank Steve Barker, Ann Russell and Albert Benthien for helpful comments and suggestions in preparing this article. Jenney Hall helped writing this article for the previous edition.

Introduction

Marine carbonates represent the major component of deep-sea sediments (Figure 1; Table 1). The distribution of carbonates throughout the world's oceans reflects the interplay between production in the surface ocean and dissolution, either in the water column, or at the seafloor before final burial. Since the modern rate of carbonate production is several times greater than the global burial rate, dissolution is an important term. The dissolution of carbonates in the deep sea is ultimately controlled by the saturation state of mean ocean water, which itself is a function of the balance between the rate of supply (through weathering) and burial of carbonate at the sea floor. In this way, the system can be thought of as self-regulating. The importance of carbonate dissolution within the global carbon cycle can be appreciated by its relation to mean ocean saturation and atmospheric CO₂. As a rule of thumb, increased dissolution will result from increased levels of CO₂ and a corresponding decrease in ocean saturation state. Past changes in atmospheric CO₂ have been linked to changes in carbonate dissolution intensity. Similarly, much of the CO₂ currently emitted by fossil fuel burning will ultimately be sequestered by an increase in deep-sea carbonate dissolution.

Global Distribution of Deep-Sea Carbonates

Surface Production

Almost all the carbonate in deep-sea sediments is manufactured by marine organisms living in the top few hundred meters of the water column. Various species of phytoplankton and zoo plankton produce calcium carbonate (CaCO₃) shells or platelets, that fall to the seafloor after death. Some organisms build tests made of calcite (e.g., coccolithophores and Foraminifera) while others (e.g., pteropods) form aragonite shells. Differences in the carbonate mineral and form result in different distributions with water depth due to their varying solubilities (see the Section 'Mechanisms of Carbonate Dissolution').

The primary control on the distribution of deep-sea carbonates is therefore the pattern of biological production in the surface ocean (Figure 1). Carbonate-rich sediments (oozes) are to be found beneath highly productive regions such as coastal or equatorial upwelling zones (a notable exception being the Southern Ocean), whereas oligotrophic areas are associated with sediments lower in carbonate content.

Dissolution in the Deep Sea

One of the most striking features of ocean sedimentation is the dramatic decrease in the carbonate content of seafloor sediments with increasing water depth. Topographic highs such as mid-ocean ridges tend to be draped in carbonate-rich oozes,

whereas abyssal depth sediments are almost devoid of carbonates (Figure 2). The transition between these two realms is a zone, several hundred meters wide, over which the CaCO₃ content drops from perhaps 85–95% to almost zero. The top of this zone (where CaCO₃ content starts to decrease rapidly) is generally termed the sedimentary lysocline (this term has also been applied to the entire transitional zone). The depth below which %CaCO₃ is effectively zero (where the flux of carbonate to the seafloor is matched by the rate of dissolution) is termed the carbonate compensation depth (the calcite compensation depth, CCD, is deeper than the aragonite compensation depth, ACD, due to the greater solubility of aragonite; see the Section 'Mechanisms of Carbonate Dissolution'). Understanding why this transition occurs and the overall role of carbonate dissolution within the global carbon cycle requires an appreciation of certain thermodynamic and kinetic considerations.

Thermodynamics of the Carbonate System in Seawater

Dissolved Inorganic Carbon, DIC

The dissolution of carbonate in seawater is intimately related to the marine carbon dioxide (CO₂) system. CO₂ dissolved in seawater exists in three inorganic forms: CO₂ (aq.) (aqueous CO₂), HCO₃[−] (bicarbonate ion), and CO₃^{2−} (carbonate ion). A fourth form, H₂CO₃ (carbonic acid), is present only in very low concentrations and is generally considered in combination with CO₂ (aq.) and denoted as CO₂:

$$[\text{CO}_2] = [\text{CO}_2(\text{aq.})] + [\text{H}_2\text{CO}_3] \quad [1]$$

Here square brackets denote the stoichiometric concentrations (molarity or mol kg^{−1}). The total dissolved inorganic carbon (DIC or ΣCO₂) in seawater is therefore defined as

$$\text{DIC} \equiv \Sigma\text{CO}_2 = [\text{CO}_2] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}] \quad [2]$$

Under equilibrium conditions (no net exchange of CO₂ between air and sea), the concentration of CO₂ in the surface ocean is related to the fugacity (or partial pressure) of CO₂ in the atmosphere according to Henry's law (the fugacity of a gas is similar to its partial pressure but allows for its nonideality):

$$\text{CO}_2(\text{g}) \stackrel{K_0}{=} \text{CO}_2(\text{aq.}) \quad [3]$$

Table 1 Global distribution of the major sedimentary types

Component	Atlantic	Pacific	Indian	World ocean
Calcareous ooze	68	36.2	54.3	47.7
Siliceous ooze	6.7	14.7	20.4	14.2
Red clay	25.3	49.1	25.3	38.1

Figure 1 Global distribution of dominant sedimentary types. Reprinted from Thurman HV and Trujillo AP (2002) *Essentials of Oceanography*, 7th ed. Upper Saddle River: Prentice-Hall.

where K_0 is the solubility coefficient of CO_2 in seawater:

$$K_0 = [\text{CO}_2]/f \text{CO}_2 \quad [4]$$

The dissolved carbonate species are related by the following equilibria:

where K_1 and K_2 are the first and second dissociation constants of carbonic acid (which do not differentiate between $\text{CO}_2(\text{aq.})$ and H_2CO_3). Thus, the system may be simplified to

It is most common to use the stoichiometric equilibrium constants, K_1^* and K_2^* , which are defined as

$$K_1^* = [\text{H}^+][\text{HCO}_3^-]/[\text{CO}_2] \quad [9]$$

$$K_2^* = [\text{H}^+][\text{CO}_3^{2-}]/[\text{HCO}_3^-] \quad [10]$$

K_1^* and K_2^* are dependent on temperature (T), salinity (S), and pressure (P) (Table 2, Figure 3). Expressions for $K_{0,1,2}$ have been determined repeatedly and the reader is referred to DOE (1994) for current recommended usage and references.

The partitioning of DIC between CO_2 , HCO_3^- , and CO_3^{2-} can be usefully illustrated with a Bjerrum plot (Figure 3). It can be seen that, for typical ocean water, HCO_3^- dominates ($\sim 90\%$), followed by CO_3^{2-} . CO_2 represents only a few percent of the total dissolved inorganic carbon in seawater. This biasing away from CO_2 explains why the oceanic carbon reservoir is so much (some 50–60 times) larger than the atmosphere and

leads to the thought that the oceans must play an important role in controlling atmospheric CO_2 levels.

It can also be seen from Figure 3 that $[\text{HCO}_3^-]$ is relatively constant for average oceanic pH values. This leads to a valuable rule of thumb; the concentration of carbonate ion, $[\text{CO}_3^{2-}]$, is inversely related to $[\text{CO}_2]$. This generalized statement can be derived numerically, by combining Eqns [9] and [10]:

$$K_1^*/K_2^* = [\text{HCO}_3^-]^2/[\text{CO}_2]/[\text{CO}_3^{2-}] \quad [11]$$

Since K_1^* , K_2^* , and $[\text{HCO}_3^-]$ are effectively constant for a given T , S , and P , Eqn [11] reduces to

$$[\text{CO}_2]/[\text{CO}_3^{2-}] \approx \text{constant} \quad [12]$$

From Eqn [11] we may also derive the pH reaction

Alkalinity, TA

The total alkalinity (TA) of seawater may be defined as the charge difference between the major conservative (concentration unaffected by changes in pH, pressure, or temperature) cations and anions:

$$\text{TA} = \Sigma \text{conservative cations} - \Sigma \text{conservative anions}$$

$$\text{TA} \approx ([\text{Na}^+] + 2[\text{Mg}^{2+}] + 2[\text{Ca}^{2+}] + [\text{K}^+]) - ([\text{Cl}^-] + 2[\text{SO}_4^{2-}]) \quad [14]$$

The small excess positive charge (~ 2 as compared with $\sim 600 \text{ mmol kg}^{-1}$ total positive charge concentration) is balanced by contributions from carbonate, borate, and water alkalinities (Figure 4):

Figure 2 %CaCO₃ in core-top sediments from the Atlantic and Pacific Oceans. Carbonate is preserved to significantly deeper depths in the Atlantic. Reprinted from Broecker WS and Peng T-H (1982) *Tracers in the sea*. Palisades: Eldigio Press.

Figure 3 Bjerrum plot for the carbonate system in seawater for various P , T , S . Blue, red, and green represent [CO₂], [HCO₃⁻], and [CO₃²⁻], respectively. Heavy curves are for $S=35$, $T=25$ C, $P=0$ dbar. Narrow curves are for $S=35$, $T=0$ C, $P=0$ dbar, dashed curves are $S=35$, $T=0$ C, $P=3000$ dbar. Note that the pK^* values ($= -\log_{10} (K^*)$) for K_1^* and K_2^* are equal to pH when [HCO₃⁻] = [CO₂] and [CO₃²⁻] = [HCO₃⁻], respectively. Shaded area represents typical ocean pH values.

$$\text{TA} \approx \text{PA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{B}(\text{OH})_4^-] + [\text{OH}^-] - [\text{H}^+] \quad [15]$$

where PA is the practical alkalinity (alkalinity for most practical purposes). In fact, carbonate alkalinity (CA) is by far the most

important contributor to TA, which leads to a useful approximation:

$$\text{TA} \approx \text{CA} = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] \quad [16]$$

Since [CO₂] is only a minor component of ΣCO_2 ,

$$\Sigma\text{CO}_2 \approx [\text{HCO}_3^-] + [\text{CO}_3^{2-}] \quad [17]$$

which leads to

$$[\text{CO}_3^{2-}] \approx \text{TA} - \Sigma\text{CO}_2 \quad [18]$$

Balance between DIC and TA

Alkalinity is delivered to the oceans by continental weathering and hydrothermal exchange and is lost mainly through sedimentary CaCO₃ burial and reef formation. Weathering or burial of CaCO₃ adds or removes TA and DIC in the ratio 2:1. Therefore, an increase in one or other of these terms will cause a change in [CO₃²⁻] (Eqn [18]) and therefore $p\text{CO}_2$ (see the Section ‘Changes in Carbonate Dissolution through Time’). Similarly, the manufacture or dissolution of CaCO₃ within the marine system causes a decrease or increase in TA and DIC in a 2:1 ratio. This means that the formation of CaCO₃ actually causes an increase in $p\text{CO}_2$ (Figure 5).

Figure 4 Charge balance for the major ions in seawater. The small excess positive charge of the conservative cations over conservative anions is balanced (mainly) by $[\text{HCO}_3^-]$, $[\text{CO}_3^{2-}]$ and $[\text{B}(\text{OH})_4^-]$ with minor contributions from $[\text{OH}^-]$ and $[\text{H}^+]$. Reprinted from Zeebe RE and Wolf-Gladrow D (2001) *CO₂ in Seawater: Equilibrium, Kinetics, Isotopes*. Amsterdam: Elsevier.

Figure 5 DIC versus TA for the formation and dissolution of CaCO_3 in seawater. Contours are constant $p\text{CO}_2$. Formation of CaCO_3 from its dissolved constituents causes a decrease in TA and DIC in the ratio 2 : 1 and a corresponding increase in $p\text{CO}_2$. The supply of CaCO_3 to the oceans from weathering (or its burial as sediments) also increases (or decreases) TA and DIC in the ratio 2 : 1.

Determining Carbonate Parameters

It is not possible to measure the individual species of the carbonate system directly. However, the four parameters, DIC, TA, $f\text{CO}_2$, and pH, can be determined. From a knowledge of any two of these parameters, along with temperature, salinity, and pressure, it is possible to calculate all six (ΣCO_2 , $[\text{CO}_3^{2-}]$, $[\text{HCO}_3^-]$, $[\text{CO}_2]$, pH, TA).

Mechanisms of Carbonate Dissolution

Thermodynamics

Efforts to understand the mechanisms of carbonate dissolution have involved many laboratory and field-based studies on both synthetic and biogenic carbonates. However, there remains considerable uncertainty regarding the specific parameters involved.

Equilibrium solution of calcium carbonate in seawater may be expressed as

The stoichiometric solubility product, K_{sp}^* is then defined as

$$K_{\text{sp}}^* = [\text{Ca}^{2+}]_{\text{sat}} [\text{CO}_3^{2-}]_{\text{sat}} \quad [20]$$

where the subscript 'sat' refers to the concentration at saturation. The tendency for CaCO_3 to dissolve in seawater depends on the degree of saturation (Ω) of the surrounding seawater with respect to the specific mineral phase in question (calcite or aragonite):

$$\Omega = [\text{Ca}^{2+}][\text{CO}_3^{2-}]/K_{\text{sp}}^* \quad [21]$$

where $[\text{Ca}^{2+}]$ and $[\text{CO}_3^{2-}]$ are the concentrations in solution. Since the concentration of Ca^{2+} in seawater is relatively constant, we can make the approximation

$$\Omega = [\text{CO}_3^{2-}]/[\text{CO}_3^{2-}]_{\text{sat}} \quad [22]$$

When $\Omega=1$, the system is at equilibrium and should be stable. $\Omega<1$ indicates that the solution is undersaturated with respect to carbonate and we should expect dissolution to occur. When $\Omega>1$, the solution is said to be supersaturated and, thermodynamically, we may expect precipitation of carbonate. However, due to complexities such as the composition of seawater, spontaneous precipitation is rare (see Morse and He, 1993). A widely used alternative for expressing the degree of saturation is the $\Delta[\text{CO}_3^{2-}]$ notation (Figure 8), where

$$\Delta[\text{CO}_3^{2-}] = [\text{CO}_3^{2-}] - [\text{CO}_3^{2-}]_{\text{sat}} \quad [23]$$

The value of K_{sp}^* depends on the particular mineral phase of interest and varies with temperature, salinity, and pressure such that solubility increases with decreasing temperature and increasing pressure (Figure 6; Table 2). For our concerns, pressure has the most important influence given the great depth of the ocean. The pressure dependence of carbonate solubility relates to the difference in volume occupied by the solid phase of CaCO_3 compared with the dissolved ions. The change in partial molar volume, ΔV , between solid and dissolved phases, where

Figure 6 Water-column profiles of *in situ* $[\text{CO}_3^{2-}]$ from the Atlantic and Pacific Oceans plotted with the saturation $[\text{CO}_3^{2-}]$ profiles for aragonite and calcite. Saturation horizons for aragonite and calcite in the Pacific and Atlantic are labeled A–D, respectively. *In situ* data are from WOCE (sections A05 and P15N, available from <http://cdiac.ornl.gov>). Solubility coefficients are from Mucci (1983). Pressure correction from Millero (1995).

$$\Delta V = V_{\text{Ca}} + V_{\text{CO}_3} - V_{\text{CaCO}_3} \quad [24]$$

is negative for calcite and aragonite, that is, the volume occupied by Ca^{2+} and CO_3^{2-} is smaller than when they are combined to form CaCO_3 . This explains why solubility increases with increasing water depth. Aragonite is more soluble than calcite for any given T , S , and P . It is for this reason that the saturation horizon for aragonite is shallower than for calcite (Figure 6, Table 2).

Experimental determinations of K_{SP}^* at various T and S and 1 atm pressure suggest an uncertainty of $\sim 5\%$ for both calcite and aragonite (Mucci, 1983). Difficulties in determining accurate values for ΔV (a range of $\sim 35\text{--}45 \text{ cm}^3 \text{ mol}^{-1}$ for calcite, e.g., Ingle (1975)) lead to a total uncertainty in K_{SP}^* of $\sim 11\%$ at 4 km water depth. Accordingly, our ability to define the vertical profiles of $[\text{CO}_3^{2-}]_{\text{sat}}$ (Figure 6) are similarly uncertain. Including the error associated with determining *in situ* $[\text{CO}_3^{2-}]$, our uncertainty in calculating Ω becomes $\pm 12\%$. In all, this means that we cannot define the depth of the saturation horizon in the oceans to better than $\pm 0.90 \text{ km}$ (see Emerson and Hedges (2003) for a fuller description).

From purely thermodynamic considerations, we should expect the CaCO_3 content of marine sediments to drop from a maximum value to zero precisely where the water column becomes undersaturated. But as stated earlier, the actual transition from carbonate-rich to carbonate-poor sediments occurs over a zone spanning several hundred meters with undissolved carbonate being found considerably deeper than the water-column saturation horizon. It is therefore necessary to consider the rate of CaCO_3 dissolution.

Kinetics

If solid CaCO_3 is in contact with undersaturated water, it will tend to dissolve. The rate of dissolution ultimately depends on the degree of undersaturation and therefore both $[\text{CO}_3^{2-}]$ and K_{SP}^* need to be known accurately. The most commonly employed form of kinetic rate equation for the dissolution of CaCO_3 (Morse and Berner, 1972) is given by

$$R = k(1 - \Omega)^n \quad [25]$$

where R is the rate (usually $\% \text{ day}^{-1}$), k is the rate constant (same units as R), and n is the reaction order. Determination of k and n has proved to be extremely nontrivial due to the difficulties in extrapolating between laboratory results and the real ocean and the fact that CaCO_3 dissolution in seawater is the sum of several different chemical reaction pathways and involves the effects of impurities and surface coatings as well as multiple carbonate phases. A notable uncertainty in our understanding of carbonate dissolution kinetics is highlighted by the disparity between dissolution rates obtained in the laboratory with those predicted from field observations (which are smaller by 2–3 orders of magnitude). The most extensive laboratory-based measurements of carbonate dissolution were made by Keir (1980) using a variety of biogenic and synthetic carbonates at near-equilibrium conditions. Keir obtained a reaction order of $n=4.5$ for calcite and a very wide range of rate constants depending on the form of calcite tested, in many cases k being inversely correlated with grain size. Later work by Hales and Emerson (1997) suggested that uncertainties in Keir's calculation of Ω had led to a particularly high rate order. They reinterpreted his results in terms of first-order kinetics. Using a value of $n \sim 1\text{--}2$ reduced the associated range of rate constants and reduced discrepancies between various field observations. However, differences in rate constants determined in the laboratory compared with *in situ* field experiments remain unexplained.

Shape of the Sedimentary Lysocline

The transition from carbonate-rich to carbonate-poor sediments as illustrated in Figure 2 is the ultimate expression of carbonate dissolution in the deep sea. The shape and position of the transition zone is sensitive to deep-water carbonate chemistry, the flux of CaCO_3 and refractory material, and also the flux of organic carbon and its oxidation to CO_2 (see also Archer (1991)). Interbasin differences in the depth of the lysocline are mainly due to deep-water chemistry variations. For example, dissolution occurs at much shallower depths in the Pacific than in the Atlantic Ocean (Figures 2 and 6). This is a result of mixing water masses with differing $[\text{CO}_3^{2-}]$ (North Atlantic Deep Water, NADW, has relatively high $[\text{CO}_3^{2-}]$ compared with deep water produced in the Southern Ocean) as well as the constant addition of CO_2 (and corresponding decrease in $[\text{CO}_3^{2-}]$) to deep waters by the oxidation of raining organic carbon as they progress along the ocean conveyor.

The fact that carbonate may be preserved below the depth at which the water column becomes undersaturated (i.e., where $\Omega < 1$) implies that dissolution is sufficiently slow (relative to the flux arriving at the sea floor) to allow burial. Also, diffusion of ocean water through the sediments must be slow enough to

allow pore waters to reach equilibrium saturation (by addition of CO_3^{2-} through dissolution). Higher fluxes of CaCO_3 to the sediment will tend to deepen the lysocline relative to the saturation horizon. This is apparent under certain upwelling areas (Figure 1). In regions where productivity is low, the CCD will tend to approach the saturation horizon.

The proportion of noncarbonate material (e.g., clays) will also affect the shape of the transition zone. For example, the generally thicker lysocline of the Atlantic relative to the Pacific Ocean is thought to be a consequence of a higher flux of terrigenous material to Atlantic sediments (Archer, 1996). The effect is related to the sensitivity of $\%\text{CaCO}_3$ to dissolution (see the Section 'Quantifying the Extent of Dissolution'); a lower initial CaCO_3 content will mean greater sensitivity of $\%\text{CaCO}_3$ to a given degree of dissolution (Archer, 1991).

Supralysoclineal Dissolution

Besides carbonate preservation below the saturation horizon, significant dissolution may occur above this depth. This phenomenon is the result of pore waters becoming undersaturated with respect to CaCO_3 through the addition of metabolic CO_2 by oxidation of organic carbon within the sediment (cf. eqn [13]). An early modeling study by Emerson and Bender (1981) suggested that release of respiratory CO_2 within pore waters could cause up to 50% dissolution of CaCO_3 even at the saturation horizon although the actual number is probably somewhat lower, perhaps 20–40%. *In situ* microelectrode measurements of O_2 and pH confirm that dissolution of CaCO_3 within pore waters must be occurring in response to the release of CO_2 (e.g., Hales and Emerson, (1997); Figure 7). Further studies, using *in situ* benthic flux measurements have generally confirmed this conclusion although supersaturated settings

with a high initial $\%\text{CaCO}_3$ have proved to be equivocal. R. A. Jahnke and D. B. Jahnke (2004) have suggested that the low alkalinity fluxes observed at these sites may be the result of inorganic CaCO_3 precipitation in the supersaturated sediment surface, followed by CO_2 -driven redissolution deeper in the sediments. Hales (2003) argues that the observations can be reconciled using revised estimates for the rates of respiration and dissolution.

A consequence of pore-water dissolution is that loss of CaCO_3 will tend to be more intense under highly productive regions (such as continental margins) for a given bottom water saturation. This is somewhat opposed to the notion that increased CaCO_3 production will tend to deepen the lysocline. However, Archer (1991) has shown that it is the ratio of C_{org} to CaCO_3 reaching the sediments (the benthic rain ratio) which makes the most difference to the proportion of CaCO_3 dissolved. Increasing the benthic rain ratio causes a shoaling of the sedimentary lysocline, whereas increasing the absolute flux of CaCO_3 will generally cause a deepening of the lysocline (Figure 8).

Quantifying the Extent of Dissolution

Dissolution Proxies

The importance of deep-sea carbonate dissolution within the global carbon cycle is reflected by the enumerable attempts to reconstruct the history of dissolution on various timescales. Furthermore, because dissolution can affect other paleoceanographic proxies employed to reconstruct climatic variations, it is evermore important to be able to quantitatively assess the extent of dissolution at any given location at any given time. At this time there is no perfect dissolution proxy; each suffers from

Figure 7 Pore-water profiles of (a) oxygen; (b) ΔpH ; (c) modeled ΔpH from 2,235 m water depth in the west equatorial Pacific (Ontong Java Plateau) from Hales and Emerson (1996). Measurements were made *in situ* using microelectrodes. Decreasing O_2 reflects the oxidation of organic matter and the production of respiration CO_2 . Heavy curves in (c) were computed assuming that respiration CO_2 does not cause dissolution of carbonate. Light curve is a best fit to the data. The observed pH values demand that dissolution occurs. Reprinted from Hales B and Emerson S (1996) Calcite dissolution in sediments of the Ontong-Java Plateau: *In situ* measurements of pore water O_2 and pH. *Global Biogeochemical Cycle*, 10: 527–541.

Figure 8 Results from Archer's (1991) sedimentary lysocline model. Curve numbers represent various CaCO_3 fluxes ($\text{micro-mol.cm}^{-2}.\text{yr}^{-1}$). Increasing the benthic rain ratio ($C_{\text{org}}/\text{CaCO}_3$) causes a shoaling of the lysocline, whereas increasing the absolute flux of CaCO_3 generally causes a deepening (these results are from Archer's oxic/anoxic model. Note results are plotted versus $\Delta[\text{CO}_3^{2-}]$ (cf. eqn [23]). Reprinted from Archer D (1991) Modeling the calcite lysocline. *Journal of Geophysical Research-Oceans* 96: 17037–17050.

particular difficulties, most commonly a sensitivity to changes in environmental conditions at the sea surface. It is wise therefore to consider more than one proxy at any given location. A further complication involves the offset in $[\text{CO}_3^{2-}]$ between bottom waters and pore waters. For example, in sediments above the water-column saturation horizon, dissolution can only occur under the influence of undersaturated pore waters. To infer changes in bottom-water $[\text{CO}_3^{2-}]$ would therefore require, at the very least, a knowledge of the contemporary benthic flux ratio of $C_{\text{org}}/\text{CaCO}_3$. (see **Carbon Cycle Proxies** ($\delta^{11}\text{B}$, $\delta^{13}\text{C}_{\text{calcite}}$, $\delta^{13}\text{C}_{\text{organic}}$, **Shell Weights**, B/Ca , U/Ca , Zn/Ca , Ba/Ca)).

Carbonate content (% CaCO_3)

The most apparent effect of dissolution in deep-sea sediments is the decrease in carbonate content with increasing water depth (Figure 2). However, the relationship between % CaCO_3 and the extent of dissolution is not simple and as a result % CaCO_3 is generally not considered a reliable indicator of dissolution. As described above, the carbonate content of a particular sediment is a function of the production and dissolution of CaCO_3 and dilution by noncarbonate material. Additionally, % CaCO_3 is fairly insensitive to the degree of dissolution until this becomes significant. For example, dissolving 50% of the carbonate from a sediment originally containing 90% CaCO_3 would only decrease this value by 8% (Figure 9).

Changes in species composition

Dissolution causes the thinning and breakup of Foraminifera tests and coccoliths. Different species are more or less susceptible to the effects of dissolution depending on the initial thickness of their tests as well as more cryptic differences such as crystal habit or chemical composition. These differences lead to changes in the species composition (faunal or floral assemblage) as dissolution proceeds and can be correlated with the extent of dissolution. Many variations of this type of proxy have been developed. As well as Berger's (1970) classic solubility ranking of planktonic Foraminifera species (Table 3),

other workers have considered the ratio of benthic to planktonic Foraminifera (benthic or bottom-dwelling species tending to be more resistant to dissolution) or pteropods to Foraminifera as well as coccolith assemblages. A major complication to this approach is the environmental control on initial species composition. Planktonic foraminifera species assemblages are very sensitive to the prevailing environmental conditions at the sea surface and are in fact widely used to reconstruct changes in, for example, sea-surface temperatures (SSTs) through time. This complication makes interpretation in terms of dissolution subject to significant uncertainty.

Fragmentation indices

The extent of breakup or fragmentation of Foraminifera tests during dissolution can be used to assess the overall preservation state of the sediment. This approach has been applied extensively to reconstruct dissolution intensity in a wide variety of settings. A potential problem with fragmentation indices is their nonlinearity; since a single shell can break into a number of fragments, a simple ratio of fragments to total entities tends to be oversensitive to changes at the onset of dissolution and much less sensitive as dissolution proceeds (Figure 10). This matter was addressed by Le and Shackleton (1992), who suggested taking the average number of fragments per whole shell into account.

$$\% \text{Fragment} = 100 \times (\# \text{fragments}/x) / \{(\# \text{fragments}/x) + \# \text{whole shells}\} \quad [26]$$

where x is the average number of fragments that a typical Foraminifera shell will break into (Figure 10). Another variant is to compare the number of fragments to whole shells of a single species (e.g., Mekik *et al.* (2002)).

Grain-size indices

Grain-size indices are based on the fact that progressive dissolution causes a decrease in the average grain size of a given sediment packet as entities such as Foraminifera tests break up. A typical example of this type of indicator is the proportion of coarse fraction to total sediment (e.g., % >150 μm). Grain-size

Figure 9 Illustration of the insensitivity of %CaCO₃ to dissolution until the fraction dissolved exceeds ~50%. Note in this case initial carbonate content is 90%. A lower initial value would result in increased sensitivity to dissolution. Straight arrows represent fluxes of carbonate and noncarbonate to the sediment and burial after dissolution (indicated by wavy arrows). indices are sensitive to the initial particle size distribution, for example, coccoliths versus Foraminifera, and are therefore subject to environmental change. They may also suffer from a lack of sensitivity at the onset of dissolution.

Foraminiferal shell weights

The individual weights of Foraminifera tests within a narrow size range have been correlated to bottom water [CO₃²⁻] and used to infer changes in this parameter (related to CaCO₃ dissolution, cf. Eqn [21]) through time (e.g., Broecker and Clark (2001)). Again, this proxy is subject to variations in initial shell weight, which may result from changing conditions during growth (e.g., Barker and Elderfield (2002)).

Figure 10 Dissolution causes progressive fragmentation of foraminiferal shells. Each shell will produce several fragments, leading to nonlinearity of a straightforward measure of %fragmentation (red curve). Le and Shackleton (1992) accounted for this by including a term for average number of fragments per whole shell into their fragmentation index (cf. Eqn [26], blue curve).

Observational indices

Changes in the ultrastructure of Foraminifera tests, caused by progressive dissolution, can be observed using scanning electron microscopy (SEM) (Figure 11). Various studies have employed this technique in an attempt to reconstruct the history of dissolution in different locations although difficulties

Figure 11 Scanning electron microscopy (SEM) can be used to assess the preservation state of carbonate sediments. In this case, numbers 1–4 show progressive dissolution of tests of *Globigerina bulloides*. Reprinted from Dittert et al. (2000).

may arise from changes in initial shell-wall structure as well as the inherent subjectivity of the method (this is also a problem with many of the other proxies discussed here).

Crystallinity

A relatively unexplored indicator of carbonate dissolution is the so-called crystallinity of foraminiferal calcite. Crystallinity, defined as the peak width (at half maximum height) of the (104) calcite X-ray diffraction peak, is essentially a measure of how perfect the calcite crystal lattice is. As dissolution proceeds, more poorly crystallized calcite is thought to be removed, causing a narrowing of the (104) diffraction peak. Crystallinity has been applied to core-top sediments and may, in the future, prove to be a reliable dissolution indicator, providing environmental conditions do not play a major role (Bassinot et al., 2004).

Composite indices

In order to circumvent the various difficulties associated with many of the individual proxies for carbonate dissolution, several workers have adopted so-called composite dissolution indices (CDIs). Peterson and Prell (1985) used a combination of six different measurements: %CaCO₃, a size index (>63 µm), three fragmentation indices (% whole Foraminifera, ratio of benthic to planktonic Foraminifera, and % whole *Globorotalia menardii*) and % radiolarians (ratio of radiolarians to radiolarians + whole planktonic Foraminifera).

Chemical indices

As well as indicators based on the physical effects of dissolution, various chemical proxies have been developed with the aim of directly reconstructing deep-sea carbonate system

parameters. For example, elemental ratios, such as Zn/Ca and Cd/Ca measured on benthic Foraminifera, have been applied to assess changes in deep ocean [CO₃²⁻] (e.g., Marchitto et al. (2005)) whereas the boron isotopic composition (δ¹¹B) of the same organisms has the potential for quantifying changes in surface and deep-water pH (e.g., Sanyal et al. (1995)).

Effect of Dissolution on Other Paleocceanographic Proxies

Many of the proxies employed by paleoceanographers utilize foraminiferal calcite. It has been widely shown that many of these proxies are actually susceptible to the effects of dissolution. For example, planktonic foraminiferal Mg/Ca ratios (used as a proxy for temperature) are known to decrease with progressive dissolution of the test. The actual mechanism is poorly understood but probably reflects the chemical heterogeneity of foraminiferal calcite. The effects of dissolution on Mg/Ca-derived temperatures can be significant and as such it is important to assess the state of sediment preservation before interpretation of results. Other foram-based proxies that may be affected by dissolution include δ¹¹B, δ¹⁸O, and faunal assemblages (see above).

Changes in Carbonate Dissolution through Time

From the relations described in Sections ‘Thermodynamics of the carbonate system in seawater’ and ‘Mechanisms of Carbonate Dissolution,’ it is possible to understand the importance of carbonate dissolution within the broader context of the global carbon cycle, particularly with respect to atmospheric CO₂. Our understanding of atmospheric CO₂ changes

in the past as well as the consequences of future changes depends on our understanding of their interaction with marine carbonate chemistry and CaCO_3 dissolution.

Carbonate Budgets and Carbonate Compensation

The marine carbonate cycle involves the balance between the production of CaCO_3 (mainly through biogenic processes) from its dissolved constituents, the delivery of those dissolved ingredients to the ocean from continental weathering or hydrothermal exchange, and the burial of solid CaCO_3 as sediment or reefs. The actual rates of carbonate production, burial, and the influx from weathering are sources of significant uncertainty, as discussed by Milliman and Droxler (1996) (Table 4). However, it is clear that the global production rate of carbonate is significantly greater than the rate of supply from weathering (by a factor of ~ 4 or more). This overproduction of carbonate is (approximately) balanced by dissolution; the depth of the lysocline is such that it intersects and dissolves approximately the correct proportion of sinking CaCO_3 to maintain the balance between supply and burial. As mentioned in the Section ‘Thermodynamics of the Carbonate System in Seawater,’ CaCO_3 weathering (or burial) adds (or removes) alkalinity and DIC in a ratio of 2 : 1. From Eqn [18], we see, for example, that an increase in CaCO_3 weathering will cause an increase in $[\text{CO}_3^{2-}]$ and deepening of the lysocline such that a smaller proportion of raining CaCO_3 will be dissolved, thereby regaining the balance between supply and burial. This process is known as carbonate compensation and has a timescale of adjustment of the order 4–5 ka (Broecker and Peng, 1982). Thus, changes in CaCO_3 dissolution through time may be linked with changes in weathering, the rate of carbonate production, or changes in the locus of CaCO_3 deposition (see below). (The present discussion concerns timescales of thousands of years. On longer (Myr) timescales, the control of weathering on CO_2 is rather different, being dependent on the rate of silicate weathering alone and not on the imbalance between weathering and burial rates (see Berner (2004) for a full description).) Importantly, these processes are also linked to atmospheric CO_2 by the inverse relation between CO_2 and $[\text{CO}_3^{2-}]$ (Eqn [12]).

Table 4 Global estimates for the rates of supply, production, and burial of CaCO_3 (units are 10^{12} mol CaCO_3 per year). Uncertainties are probably less than a factor of 1 for most values

Inputs	Production	Outputs (burial)
Rivers (~ 13)	Coral reefs, shelves (~ 25)	Neritic (~ 15)

Glacial–Interglacial Changes in Atmospheric CO_2

Ice-core records tell us that atmospheric CO_2 was approximately 30% lower during the Last Glacial Maximum (LGM) than the preindustrial Holocene (see CO_2 Studies). They also tell us that CO_2 has varied in tandem with the late Pleistocene glacial cycles, each cycle comprising a stepwise decline from an interglacial high of about 280 ppmv to a glacial low of about 190 ppmv followed by a more rapid increase to interglacial values during glacial terminations (Petit *et al.*, 1999). The reason for lowered atmospheric CO_2 during glacial times has been debated for more than quarter of a century and is still the subject of enquiry. However, since the oceans contain some 50–60 times more carbon than the atmosphere (see the Section ‘Thermodynamics of the Carbonate System in Seawater’), it is assumed that they must play a major role in the drawdown of CO_2 during glacial times. Currently favored mechanisms involve variations in vertical stratification and air–sea exchange in the Southern Ocean, enhanced biological activity under the influence of Fe fertilization, and changes in the dominant plankton type (see Sigman and Boyle (2000) for a review and additional references). However, any mechanism will ultimately involve interaction with the marine carbonate cycle. A few examples of mechanisms involving changing carbonate dissolution patterns are described below.

Records of % CaCO_3 from the deep Pacific Ocean show cycles of increased glacial CaCO_3 content and decreased % CaCO_3 during interglacials (Figure 12). There has been debate over whether the Pacific CaCO_3 cycles represent changes in dissolution intensity or surface ocean CaCO_3 production although dissolution is the generally favored explanation. The observation of a deeper calcite lysocline during glacial times (Figure 12) suggests that deep ocean $[\text{CO}_3^{2-}]$ was higher and could help to explain the decrease in CO_2 .

In an attempt to explain the glacial decrease in CO_2 , Berger (1982) suggested that rising sea levels associated with glacial terminations would increase the accommodation space for coral reef communities. Since coral reefs and shallow carbonate deposition account for almost half of all modern CaCO_3 burial (Table 4; Milliman and Droxler, 1996), an increase in this mode of deposition at the end of glacial times would cause global CaCO_3 burial to exceed supply, leading to a decrease in whole ocean $[\text{CO}_3^{2-}]$ and an increase in atmospheric CO_2 . This would in turn lead to a shoaling of the lysocline through compensation and a shift in the locus of carbonate deposition from the deep sea to more shallow waters. However, the mean change in lysocline depth for the glacial period is not sufficient to explain the 30% reduction in CO_2 via this mechanism. CaCO_3 dissolution actually increased in the deep Atlantic as a consequence of low $[\text{CO}_3^{2-}]$ Antarctic Bottom Water (AABW) invading the glacial deep Atlantic (Barker *et al.*, 2004). In fact, an estimate of global deep-sea CaCO_3 accumulation during the last glacial period suggests that it was probably very similar to the modern day (Catubig *et al.*, 1998). Furthermore, since the deglacial rise in CO_2 preceded the rise in sea level, it cannot have been driven mainly by changes in shallow-water accommodation space.

Another suggestion was made by Archer and Maier-Reimer (1994). This involved the influence of pore-water CaCO_3 dissolution and the benthic rain ratio of C_{org} to CaCO_3 (see

Figure 12 Reconstructed sedimentary lysocline in the equatorial Pacific made by combining several records of %CaCO₃ from different water depths (Farrell and Prell, 1989). Glacial periods are characterized by a deepened and narrower transition zone suggesting better carbonate preservation. Reprinted from Farrell BF and Prell W (1989) Climatic change and CaCO₃ preservation; an 800,000 year bathymetric reconstruction from the Central Equatorial Pacific Ocean. *Paleoceanography* 4: 447–466.

the Section ‘Shape of the Sedimentary Lysocline’. By increasing the production ratio of organic carbon to inorganic carbonate (e.g., by increasing the ratio of diatom to coccolithophore production), Archer and Maier-Reimer argued that increased supralysoclineal dissolution would cause carbonate supply to exceed burial, thereby raising [CO₃²⁻] and lowering CO₂. In this scenario, the depth of the sedimentary lysocline would not need to change by very much since it would shoal relative to a deepened saturation horizon. Although the ‘rain-ratio’ hypothesis escapes some of the problems associated with the coral reef hypothesis, it has not yet passed the rigors of validation (e.g., there are difficulties associated with the width of the predicted transition zone (Sigman *et al.*, 1998)). Thus the search for a viable explanation for the glacial lowering of atmospheric CO₂ continues. In all likelihood, it will comprise a combination of several mechanisms rather than a single process.

Carbonate Dissolution in the Future: Sequestration of Anthropogenic CO₂

Atmospheric CO₂ has increased by around 90 ppmv (~30%) since the start of the industrial revolution. However, this increase reflects only about half of the total CO₂ added; most of the rest has been taken up by the oceans. The oceans provide a buffer to increasing CO₂ by reaction with CO₃²⁻, thereby lowering the saturation state. This has consequences for marine life in the surface ocean but will also result in deep-sea CaCO₃ dissolution. In fact, much of the CO₂ released by fossil fuel burning will ultimately be neutralized by CaCO₃ dissolution in the deep sea. Estimates of the inventory of deep-sea CaCO₃ available for CO₂ neutralization are of the order 2000–5000 Gt C (Archer *et al.*, 1997). These can be compared to a global

inventory of fossil fuel reserves of ~5000 Gt C (Sundquist, 1985). Modeling studies (Archer *et al.*, 1997, 1998) suggest that on timescales of hundreds of years, 70–80% of anthropogenic CO₂ will dissolve into the oceans. Neutralization by CaCO₃ dissolution will occur on timescales of thousands of years and will eventually account for 60–70% of total CO₂ emissions.

Introduction

In the ocean, the distribution of sea surface and bottom water temperature (BWT) and salinity is perhaps the best representation of the state of the climate system, as the ocean plays a fundamental role in the evolution of Earth's climate. Therefore, determining the past temperature evolution of the ocean is key for understanding Earth's climate history. Among the most often used elemental proxies of paleotemperature are Mg/Ca in planktonic Foraminifera and Sr/Ca in corals as recorders of sea surface temperature (SST) and Mg/Ca in benthic Foraminifera and ostracodes as proxies of BWT. Mg, Sr, and Ca have relatively long oceanic residence times, about 13 My for Mg, 5 My for Sr, and 1 My for Ca, implying nearly constant Mg-, and Sr- to- Ca ratios in seawater on timescales of less than a million years. A clear advantage of these carbonate-based thermometers is that coupling $\delta^{18}\text{O}$ and Mg/Ca measurements in Foraminifera, or Sr/Ca in corals, potentially provides a novel way to adjust for the temperature-dependency of $\delta^{18}\text{O}$ in CaCO_3 minerals and isolate the record of seawater $\delta^{18}\text{O}$ ($\delta^{18}\text{O}_{\text{seawater}}$; Mashiotto et al., 1999), which can then be used to reconstruct local changes in evaporation–precipitation (and by inference salinity; e.g., Lea et al., 2000), advection of water with different seawater oxygen isotopic composition ($\delta^{18}\text{O}_{\text{seawater}}$) and provide valuable information about changes in continental ice volume (e.g., Lear et al., 2000).

Thermodynamic Effects on Mg and Sr Coprecipitation in Carbonates

Among the alkaline earth elements, Mg^{2+} and Sr^{2+} form the most important solid solutions with carbonates. Because of the difference in the ionic radii between Sr^{2+} (large) and Mg^{2+} (small), SrCO_3 is isostructural with the aragonite crystal cell (orthorhombic), whereas MgCO_3 is isostructural with calcite (rhombohedral). The Mg/Ca and Sr/Ca ratios in CaCO_3 minerals depend on two factors: the Mg/Ca and Sr/Ca activity ratios of ocean water, and the distribution coefficients of Mg/Ca and Sr/Ca between calcite, aragonite, and seawater, respectively. These relationships are expressed as $D_{\text{El}} = (\text{El}/\text{Ca})_{\text{mineral}}/(\text{El}/\text{Ca})_{\text{seawater}}$, where D_{El} is the empirical homogeneous distribution coefficient calculated based on the molar concentration ratios of Mg/Ca and Sr/Ca in calcite, aragonite, and seawater, respectively. At equilibrium, the partitioning constant between the two pure mineral phases depends on temperature, as the substitution of Mg into calcite and Sr into aragonite, are both associated with a change in enthalpy or heat of the reaction, which is sensitive to temperature. As the substitution of Mg into calcite is an endothermic reaction, the Mg/Ca ratio of calcite is expected to increase with increasing temperature (Rosenthal et al., 1997). In contrast, the

substitution of Sr into aragonite is an exothermic reaction, so the Sr/Ca ratio of aragonite should be inversely correlated with temperature.

Based on thermodynamic considerations, Rosenthal et al. (1997) and Lea et al. (1999) proposed an exponential temperature dependence of Mg uptake into calcite of about 3% per K. This prediction is consistent with experiments of Mg incorporation into inorganically precipitated calcites; inorganic coprecipitation experiments of Sr with aragonite show a weak inverse linear dependence on temperature. However, as instructive as these data may be, biologically mediated processes are rarely at thermodynamic equilibrium. For example, Foraminifera contain 1–2 orders of magnitude lower Mg than found in marine inorganic calcites. Such offsets suggest that biological processes exert a major influence on the coprecipitation of metals in biogenic carbonates, thus highlighting the need for species-specific empirical calibrations.

Foraminiferal Mg/Ca Paleothermometry

Temperature Calibrations of Mg/Ca in Planktonic Foraminifera

The temperature dependence of Mg uptake into planktonic foraminiferal tests has been determined using three different approaches: (i) controlled culture experiments in which temperature is fixed independently of other environmental parameters (e.g., light, salinity, and pH); (ii) measurements of planktonic Foraminifera from sediment trap time series in sites characterized by significant seasonal variability in SST; (iii) analyses of fossil (dead) Foraminifera tests obtained from surface sediments, typically from core tops. A summary of published multiple-, and single-species calibrations is given in Table 1. At present, Mg/Ca calibrations are mostly expressed as an exponential dependence of temperature in the form: $\text{Mg}/\text{Ca} \text{ (mmol mol}^{-1}\text{)} = B e^{AT}$ where A and B are the exponential and pre-exponential constants, respectively, and T is temperature in $^{\circ}\text{C}$. Justification for the choice of exponential fit to the empirical data comes primarily from the thermodynamic prediction of exponential response. In this relationship, the exponential constant reflects the Mg/Ca response to a given temperature change (in $\text{mmol mol}^{-1}^{\circ}\text{C}^{-1}$), implying increased sensitivity with temperature. The pre-exponential constant determines the absolute temperature.

Culture-based calibrations are available for several species including *Globigerinoides sacculifer* (Nürnberg et al., 1996), *Globigerinoides ruber* (white; Kisakurek et al., 2008), *Orbulina universa* (Lea et al., 1999; Russell et al., 2004), *Globigerina bulloides* (Lea et al., 1999; Mashiotto et al., 1999), and *Neoglobobulimina papyderma* (dextral; Langen et al., 2005) (Figure 1(a)). Combined, the available experiments suggest a temperature sensitivity of $9.4 \pm 0.9\%$ (1 S.D.) change in Mg/Ca per $^{\circ}\text{C}$, thus providing the strongest direct evidence for temperature control

Table 1 Summary of published Mg/Ca–temperature calibrations for multiple and single species of planktonic Foraminifera (Mg/Ca in mmol mol⁻¹ and *T* in °C). Except when noted, all calibrations are based on exponential equations $Mg/Ca = A e^{BT}$

on planktonic foraminiferal Mg/Ca, much in the same way that inorganic experiments supported the thermodynamic expectations. Sediment trap calibrations provide additional support to the dominant temperature control. The sediment-trap based multispecies calibration of Anand et al. (2003) from the Sargasso Sea (Figure 1(b)) is in good agreement with culture-based calibrations, suggesting a multispecies temperature sensitivity of $9 \pm 0.3\%$ per °C. Subsequent calibrations of *G. ruber* (white) from sediment traps in the Indian Ocean, off Java Island (Indonesia), and the South China Sea yield consistent results (Huang et al., 2008; Mohtadi et al., 2009). Consistent with these results, the multispecies core-top calibration of Elderfield and Ganssen (2000), reevaluated by Rosenthal and Lohmann (2002) suggests temperature sensitivity of $9.5 \pm 0.5\%$ per °C (Figure 1(c)).

A main advantage of multispecies calibration is the large temperature range it provides, which may offer a broader base

for statistical analysis. However, offsets among species can bias the calibration, and therefore, should be considered when choosing the appropriate equation, be it a single- or a multi-species calibration (Regenberg et al., 2009). Indeed, such offsets in Mg/Ca among individual species stress the need for single-species calibrations. Although there is significant variability among the different equations, the median exponential value of the 27 calibrations given in Table 1 is $8.5 \pm 1.6\%$ (1 S.D.) per °C (average 8.2%), in accordance with the multispecies calibrations. Collectively, a sensitivity of $9 \pm 1\%$ per °C seems to be a robust feature of planktonic Foraminifera; differences among calibration may reflect additional controls. It is also noteworthy that for single-species calibrations based on a narrow temperature range, a linear regression might provide a better fit to the data. The pre-exponential constant (*B*) differs significantly among calibrations, for both the same and

Figure 1 Mg/Ca–temperature calibrations based on: (a) culture experiments (data from (1) Lea et al. (1999), (2) Russell et al. (2004), (3) (Langen et al. (2005), (4) Kisakurek et al. (2008)); (b) sediment traps from the Sargasso Sea (Anand et al., 2003); (c) core tops (Elderfield and Ganssen, 2000) (regression line 1 from Elderfield and Ganssen (2000), line 2 from Rosenthal and Lohmann (2002) based on the same data set).

different species. This high variability reflects a combination of several factors including intra- and interspecies variability (Anand et al., 2003; Elderfield and Ganssen, 2000), diagenetic overprints including postdepositional dissolution (Rosenthal and Lohmann, 2002), contamination from sedimentary contaminants (e.g., Lea et al., 2005; Pena et al., 2005, 2008). It is also important to note that methodological biases among laboratories should be considered and accounted for when comparing data sets cleaned with and without the reductive step (Rosenthal et al., 2004). It follows, that the accuracy of Mg/Ca thermometry is often better in estimating relative changes in seawater temperatures (i.e., anomalies) than absolute temperatures.

The good agreement between the core-top, sediment trap and culture-based calibrations also provides strong evidence that the temperature signal imprinted during the test formation is reliably transferred into the sediment although, as discussed below, secondary effects of salinity and pH on the calcification process and postdepositional alteration may complicate the interpretation of Mg/Ca records in terms of variability due strictly to temperature.

Inter- and Intraspecies Variability

Interspecies variability in Mg/Ca is generally correlated with their calcification depth. Accordingly, shallow mix-layer dwellers (e.g., *G. ruber* and *G. sacculifer*) have high Mg/Ca, whereas deep dwellers (e.g., *Pulleniatina obliquiloculata*, *Globigerinoides inflata*, *Globigerinoides truncatulinoides*), are characterized by relatively low Mg/Ca (Rosenthal and Boyle, 1993). By assuming specific calcification depth to each foraminiferal species, and using the appropriate calibration (Anand et al., 2003; Cleroux et al., 2008; Regenberg et al., 2009; Skinner and Elderfield, 2005) one can reconstruct the temperature structure of the upper thermocline (e.g., Groeneweld and Chiessi, 2011; Xu et al., 2008). However, although it is common to assign planktonic Foraminifera specific calcification depths, it is also well known that many species continue to calcify while migrating vertically through the water column and some species, such as *G. sacculifer*, also add an outer calcite crust prior to reproduction (aka ‘gemetogenic crust’) at depths significantly deeper (and colder) than their principal habitat depth. These processes are likely to cause significant variability in the Mg

distribution within and among Foraminifera tests, which should be linked to changes in calcification temperature. It follows, that the 'whole test' Mg/Ca composition most commonly used for temperature reconstructions represents a weighted average of calcite layers formed at different depths/temperatures. This is less of an issue for the shallow, mixed-layer species of *G. ruber* and *G. sacculifer* and more critical for deep species such as *P. obliquiloculata*, *Neogloboquadrina dutertrei*, *Globigerinoides tumida* and *G. truncatulinoides*.

There is also significant size-dependent variability in Mg/Ca ratios among tests of the same species. Mg/Ca increases with increasing test size in most species, possibly because small individuals calcify faster than large individuals (Elderfield et al., 2002) or because larger individuals spend relatively more time near the sea surface, where the water is warmer and the higher light intensity increases symbiont photosynthetic activity, which in turn allows growth to larger sizes (Honisch and Hemming, 2004; Spero and Lea, 1993). In addition, Mg/Ca can vary among different morphotypes of the same species, reflecting differences in growth season (e.g., the white vs. pink variety of *G. ruber*; Anand et al., 2003) or depth habitat (e.g., *G. ruber* s.s. vs. *G. ruber* s.l.; Steinke et al., 2005). The intraspecific variability implies that Mg/Ca analyses and calibration should be performed on the same morphotypes and within a narrow size range. Also, when possible, the same size fraction should be used for both Mg/Ca and isotopic analyses.

Studies using microanalytical techniques also reveal large variability in Mg/Ca (and other trace elements) within and among individual tests that is apparently too large to be explained by the temperature change due to the vertical migration experienced by the different species during their adult life cycle (Hathorne et al., 2009; Kunioka et al., 2006; Sadekov et al., 2008). The pattern of Mg/Ca variation is significantly different between symbiont-bearing and symbiont-free species (Eggins et al., 2003, 2004). Tests of symbiont-bearing Foraminifera show cyclic variations between high and low Mg/Ca layers within individual chambers, which are largely absent from symbiont-free species (Sadekov et al., 2005). There are also indications that high Mg/Ca ratios are associated with organic-matrix rich bands (Kunioka et al., 2006). Nonetheless, despite the large, hitherto unexplained, intratest variability, it is widely accepted now that whole test Mg/Ca measurements produce estimates that closely match measured temperatures along the water column at the assumed individual species calcification depth and over a large geographical extent (Eggins et al., 2003; Hathorne et al., 2009; Sadekov et al., 2008, 2009, 2010).

Secondary Nontemperature Effects

Salinity and pH effect

Culture studies have provided evidence for a positive relationship between planktonic foraminiferal Mg/Ca and seawater salinity (Lea et al., 1999; Nürnberg et al., 1996) and arguably an inverse dependence on pH (Lea et al., 1999; Russell et al., 2004). These experiments have documented a relatively small salinity effect, about $6 \pm 4\%$ change in Mg/Ca per salinity unit (psu) over a salinity range of 20–45 for *G. ruber*, *G. sacculifer* and *O. universa* (Dueñas-Bohórquez et al., 2009; Kisakurek et al., 2008; Lea et al., 1999). In contrast, core-top calibrations suggest substantially higher and quite variable salinity

dependence. For *G. ruber*, these calibrations suggest salinity sensitivity of about 14%, 27%, and up to 40% per psu. for sediments from the equatorial Indian-Pacific Oceans (Mathien-Blard and Bassinot, 2009), Atlantic Ocean (Arbuszewski et al., 2010), and Mediterranean Sea (Ferguson et al., 2008), respectively (although note that the very high estimates might reflect contamination by secondary high-Mg overgrowths; Hoogakker et al., 2009). Interestingly, the core-top calibrations suggest that the dependence on salinity is significantly higher than suggested from culture experiments and apparently increases with salinity. Indeed, a recent paper suggests little or no Mg/Ca dependence at low salinities (32–34) and a high dependence at high salinities (>35) (Arbuszewski et al., 2010).

The pH effect on planktonic Foraminifera is still uncertain. In early culture experiments, Mg/Ca in *O. universa* and *G. bulloides* decreased by about $7 \pm 6\%$ per 0.1 pH unit (Lea et al., 1999; Russell et al., 2004). Subsequent culture experiments of *G. ruber* and *G. sacculifer* suggest a negligible effect at modern seawater pH or $[\text{CO}_3]$ concentration and an inverse relationship below that (Dueñas-Bohórquez et al., 2009; Kisakurek et al., 2008). Indeed, the $[\text{CO}_3]$ effect may differ among species and also depend on other environmental conditions. For example, a sediment trap study in the Antarctic Ocean shows significant positive relationship between Mg/Ca of *N. pachyderma* (sinistral) and surface water $[\text{CO}_3]$ (Hendry et al., 2009). This and complementary studies in the Nordic Seas (Kozdon et al., 2009; Meland et al., 2006) suggest that temperature may exert the dominant control on Mg/Ca in *N. pachyderma* (s) above 3 °C, whereas below that there is an additional saturation effect that might mask the temperature dependence. It could also be that long-term adaptation in the field induces a different response than observed under short-term culture experiments.

Whereas more studies are required to accurately determine the sensitivity of Mg/Ca to different environmental conditions, a new generation of equations may be required in order to more accurately describe the dependence of planktonic foraminiferal Mg/Ca on temperature, salinity, and carbonate concentrations. These multivariate equations should be used in future studies and for reappraising published records (e.g., Arbuszewski et al., 2010; Mathien-Blard and Bassinot, 2009).

Dissolution Effects

Core-top studies along bathymetric transects indicate a systematic decrease in Mg/Ca ratios of planktonic Foraminifera with increasing depth, independent of the overlying SSTs, thereby suggesting that foraminiferal Mg/Ca is altered by post-depositional dissolution on the seafloor, driven by the depth-dependent decrease in carbonate saturation levels (Dekens et al., 2002; Rosenthal et al., 2000). The dissolution effect is significantly stronger below the lysocline, although the exact response depends on the species (Regenberg et al., 2006). It has been argued that the systematic decrease in Mg/Ca ratios of planktonic Foraminifera is likely caused by preferential dissolution of the Mg-rich and more dissolution-susceptible calcite (Brown and Elderfield, 1996), which results in a decrease in the whole test Mg/Ca ratio that shifts the temperature estimates toward apparently colder values (Rosenthal et al., 2000). The decrease in Mg/Ca with depth is higher in

nonspinose, thermocline dwelling species (e.g., *G. tumida* and *N. dutertrei*) than in spinose, shallow dwelling species (*G. ruber* and *G. sacculifer*), in accordance with the larger range of temperatures over which the deep dwellers calcify (Brown and Elderfield, 1996; Dekens et al., 2002; Huang et al., 2008).

Various approaches have been offered to account for dissolution effects on Mg/Ca. Several studies propose that combining core-top measurements, where the magnitude of the depth-dependent decrease of Mg/Ca has been determined with independent estimates for past shifts in lysocline depth, could be used to estimate the bias in Mg/Ca–temperatures due to dissolution effects (Dekens et al., 2002; Lea et al., 2000; Regenberg et al., 2006). Applying this approach to two Pacific records, these studies suggest a potential error of 0.5 °C in the estimates of the tropical Pacific glacial–interglacial temperature amplitude. This approach, however, does not quantify the dissolution effects on specific samples, which might respond more to changes in pore-water chemistry than to shifts in the hydrographic lysocline depth. Taking a different approach, Rosenthal and Lohmann (2002) suggested that the relationship between size-normalized test weight, and the dissolution-driven decrease in Mg/Ca, could be used for correcting down core Mg-based temperature estimates for dissolution effects. While this method is very attractive, as it directly addresses

dissolution effects experienced by a particular sample, further studies have demonstrated that the test's size–weight relationship is not strictly a function of dissolution, as initially thought, but also depends on the [CO₃] content of seawater in which they grow (Barker and Elderfield, 2002). It is possible that using multiple species at different water depths (i.e., above and below the lysocline) may provide a way to distinguish primary from postdepositional effects.

Temperature calibrations of Mg/Ca in benthic Foraminifera

Initial calibrations, largely based on the *Cibicidoides pachyderma* from a shallow bathymetric transect in Little Bahama Banks (spanning a temperature range of 5–18 °C), suggested that the temperature sensitivity of *Cibicidoides* spp. Mg/Ca is essentially identical with the ~9% increase in Mg/Ca per °C observed in planktonic Foraminifera (Lear et al., 2002; Martin et al., 2002; Rosenthal et al., 1997). Similar temperature sensitivities were observed in other benthic species including *Planulina* spp., *Oridorslis umbonatus*, and *Melonis* spp. (Lear et al., 2002), however, as is the case for planktonic Foraminifera, it was also noted that interspecies offsets in benthic Foraminifera exist for which corrections are needed (e.g., Lear et al., 2000). Subsequent studies have raised questions, however, about the accuracy of these initial calibrations (Table 2).

Table 2 Summary of published Mg/Ca–temperature calibrations for benthic Foraminifera (Mg/Ca in mmol mol^{−1} and temperature in °C)

First, it has been argued that the shallow Little Bahama Banks samples are compromised by diagenetic calcite overgrowths enriched in Mg, thus yielding an apparently high exponential dependence on temperature. New calibration studies of *C. pachyderma* from depth transects in the Florida Straits and Great Bahama Banks, in areas where the problem of diagenetic calcite overgrowths is apparently minimal, suggest a linear relationship between Mg/Ca and BWT with a sensitivity of $\sim 0.12 \text{ mmol mol}^{-1} \text{ }^{\circ}\text{C}^{-1}$ (Table 2) for the temperature range from 5.8 to 18.6 $^{\circ}\text{C}$ (Marchitto et al., 2007). This calibration has been replicated in Little Bahama Banks by Curry and Marchitto (2008) who used a microanalytical technique to avoid contamination by diagenetic overgrowths.

Secondly, in deep waters the degree of CaCO_3 saturation starts to exert a significant control on the incorporation of Mg into benthic foraminiferal tests, thus altering the Mg/Ca-temperature relationships (Elderfield et al., 2006; Martin et al., 2002; Rosenthal et al., 2006). New calibrations based on global datasets suggest a $\Delta[\text{CO}_3]$ -Mg/Ca sensitivity of $\sim 0.009 \text{ mmol mol}^{-1} \mu\text{mol}^{-1} \text{ kg}^{-1}$ (where $\Delta[\text{CO}_3]$ is the degree of calcite bottom-water saturation) in calcitic benthic tests that, in the modern ocean, becomes increasingly important below $\sim 3^{\circ}\text{C}$ (Elderfield et al., 2006; Healey et al., 2008). There are also indications for a significant $[\text{CO}_3]$ ion effect at warmer, oversaturated waters (Bryan and Marchitto, 2008). After adjusting for the additional $\Delta[\text{CO}_3]$ effect, a sensitivity of about $0.12\text{--}0.15 \text{ mmol mol}^{-1} \text{ }^{\circ}\text{C}^{-1}$ is found in other epifaunal species including *Cibicidoides wuellerstorfi*, *Cibicidoides mundulus* and *Oridorsalis umbonatus* (Healey et al., 2008; Raitzsch et al., 2008; Sosdian and Rosenthal, 2009; Yu and Elderfield, 2008), consistent with the *C. pachyderma* calibration (Marchitto et al., 2007).

It is now evident that benthic foraminiferal Mg/Ca thermometry is not as straightforward as initially thought, and the additional $\Delta[\text{CO}_3]$ effect needs to be constrained in any down core reconstructions of deep-water temperatures. One possible approach is using paired elemental ratios with different sensitivities for temperature and $\Delta[\text{CO}_3]$ (e.g., Mg/Ca coupled with Li/Ca or B/Ca) to correct for, or deconvolve the contribution of different environmental parameters (Bryan and Marchitto, 2008; Lear et al., 2010; Yu and Elderfield, 2008) or through using independent estimates of the carbonate ion effect (Sosdian and Rosenthal, 2009). However, the low sensitivity suggested for the above-mentioned Foraminifera and the additional $\Delta[\text{CO}_3]$ effect can also lead to large errors associated with estimating deep ocean temperatures (e.g., $\pm 2.4^{\circ}\text{C}$ for *C. pachyderma*: Marchitto et al., 2007). Alternatively, it has been argued that infaunal taxa such as *Uvigerina* sp. may be less affected by the $\Delta[\text{CO}_3]$ effect as it calcifies from saturated pore waters and thus is less affected by bottom water chemistry (Elderfield et al., 2009). The exact temperature sensitivity of *Uvigerina* species is, however, still uncertain. On the other hand, core-top calibrations suggest sensitivity of about 6–8% per $^{\circ}\text{C}$ (Elderfield et al., 2009; Lear et al., 2002), so a significantly higher sensitivity is required to explain the relatively large down core variability (Elderfield et al., 2009; Martin et al., 2002). If indeed some shallow infaunal benthic Foraminifera are free of saturation effects and characterized by high temperature sensitivity, they may offer a new tool for accurate and

precise reconstruction of past deep ocean temperatures. One promising example is the use of the shallow infaunal calcitic species, *Hyalinea balthica*, which exhibits high temperature sensitivity ($\sim 0.5 \text{ mmol mol}^{-1} \text{ }^{\circ}\text{C}^{-1}$) and no discernible $\Delta[\text{CO}_3]$ effect (Bamberg et al., 2010; Rosenthal et al., 2011).

Inferring Seawater $\delta^{18}\text{O}$ and Salinity

The $\delta^{18}\text{O}$ composition of calcareous marine fossils reflects, at a minimum, both the temperature and the isotopic composition of seawater in which the shell or skeleton was formed. The $\delta^{18}\text{O}$ of modern surface water reflects, in part, the hydrological balance between evaporation and precipitation (E/P), that is, the surface salinity. Advection can also alter $\delta^{18}\text{O}_{\text{sw}}$ by mixing waters of different salinities (or $\delta^{18}\text{O}_{\text{sw}}$). Over very long time scales, seawater $\delta^{18}\text{O}$ is also a function of the extent of continental ice sheets. Paired $\delta^{18}\text{O}$ and Mg/Ca measurements in Foraminifera allow for the adjustment of temperature-dependency of carbonate $\delta^{18}\text{O}$ and isolation of $\delta^{18}\text{O}_{\text{sw}}$ (Lea et al., 2000; Mashiota et al., 1999), which can then be used to reconstruct local changes in E/P and by inference salinity (e.g., Oppo et al., 2009; Schmidt et al., 2004; Stott et al., 2004), and provide valuable information about changes in continental ice volume (e.g., Lear et al., 2000). A major advantage of measuring both proxies on the same samples is that it allows for the determination of temporal leads and lags between variations in seawater temperature and the build-up or erosion of continental ice sheets, which is fundamental for understanding climate change.

In the past decade, the application of this method has already led to important findings. New Mg-derived SST records have contributed to our understanding of the role of the equatorial Pacific in global climate change on millennial (e.g., Koutavas et al., 2006; Linsley et al., 2010; Stott et al., 2002), orbital (e.g., Lea et al., 2000; Rosenthal et al., 2003), and secular time scales (e.g., de Garidel-Thoron et al., 2005; Wara et al., 2005). Among the most significant findings that come from these studies are: (1) the equatorial Pacific was characterized by a 'super El Nino' state during the mid-Pliocene warm period (Wara et al., 2005); (2) except for glacial-interglacial variability, Western Pacific warm pool (WPWP) SSTs were stable throughout the Pleistocene, despite Northern Hemisphere glaciations and global cooling (de Garidel-Thoron et al., 2005); (3) SST in the WPWP was 2–3 $^{\circ}\text{C}$ cooler during glacial periods than at present (e.g., de Garidel-Thoron et al., 2007; Lea et al., 2000; Linsley et al., 2010); and (4) during glacial terminations, changes in equatorial SST arguably led the Northern Hemisphere deglacial record by ~ 3000 years (Lea et al., 2000; Visser et al., 2003).

Other examples of a breakthrough offered by this new approach are benthic foraminiferal Mg/Ca records documenting the global cooling trend throughout the Cenozoic (Billups, 2003; Billups and Schrag, 2002; Lear et al., 2000, 2004; Sosdian and Rosenthal, 2009). The low-resolution seawater oxygen isotope record ($\delta^{18}\text{O}_{\text{seawater}}$) of Lear et al. (2000) suggests that the Cenozoic expansion of continental ice sheets occurred primarily in three steps: the Antarctic glaciation during the Eocene-Oligocene (E/O) transition and the middle Miocene, and the Northern Hemisphere glaciation during the Pliocene-Pleistocene. A high-resolution benthic Mg/Ca record from the

North Atlantic (Figure 2) shows two distinct cooling events: the first associated with the late Pliocene (LPT, 2.5–3 Ma) and the second preceding the transition from a dominant 41–100 ka climate variability during mid-Pleistocene (the Mid-Pleistocene Transition, 1.2–0.85 Ma; Sosdian and Rosenthal, 2009). The reconstructed $\delta^{18}\text{O}_{\text{seawater}}$ record suggests that sea level was apparently 25 ± 20 m higher than at present during the mid-Pliocene, a period considered to be a good analog for future climate. While this estimate needs to be validated, given the uncertainties in the method, it offers a new way to assess climate variability and impacts under different boundary conditions. On time scales longer than ~ 1 My, secular variations in seawater Mg/Ca need to be considered before interpreting foraminiferal Mg/Ca records strictly in terms of temperature. First, the paleotemperature equation should include a term accounting for the difference between the seawater Mg/Ca ratio in the past and in the modern ocean. Secondly, studies of various calcareous organisms suggest that the partitioning of Mg between the solution and biogenic CaCO_3 minerals is nonlinearly dependent on the Mg/Ca ratio of the seawater (Hasiuk and Lohmann, 2010; Ries, 2004; Segev and Erez, 2006). Therefore, these parameters need to be considered in order to obtain accurate reconstructions of the secular variations of ocean temperature (e.g., Cramer et al., 2011 and references therein).

Marine Ostracode Mg/Ca Paleothermometry

Studies over the past decade have provided strong evidence for the temperature dependence of Mg/Ca in marine ostracodes (Dwyer et al., 2002, and references therein). Indeed records of Mg/Ca in marine ostracodes have been used successfully for reconstructing the history of BWTs through the Pliocene and Pleistocene (e.g., Cronin et al., 2005; Dwyer et al., 1995). Ostracodes are bivalved crustaceans that grow via a process of molting. Ostracodes excrete an exoskeleton known as a carapace that in some taxa consists of 80–90% calcite and the rest of chitin and proteins. Tests of adult specimens, used in paleoceanography, are flat, typically 0.5–1 mm in length and weigh between 20 and 200 μg , thus providing a good target for geochemical analyses. Temperature calibrations are currently available for two marine, epifaunal benthic ostracodes, the deep-sea genus *Krithe* and shallow marine/estuarine genus *Loxococoncha* (Dwyer et al., 1995, 2002), both long-lived genera known since the Cretaceous. Mg/Ca ratios in these genera are significantly higher than in deep-sea benthic Foraminifera. Based on core-top calibrations, Dwyer et al. (2002) proposed a linear relationship between *Krithe* Mg/Ca and temperature, with a slope of $0.95 \pm 0.15 \text{ mmol mol}^{-1} \text{ } ^\circ\text{C}^{-1}$ or expressed as an exponential dependence of 6% per $^\circ\text{C}$, which is within the range of sensitivities observed in Foraminifera (Figure 3).

Figure 2 Plio-Pleistocene benthic foraminiferal records from Deep Sea Drilling Project (DSDP) site 607 (41° N, 32° W, 3427-m water depth) in the North Atlantic: (a) benthic oxygen isotope record ($\delta^{18}\text{O}_b$ in ‰PDB); (b) benthic foraminiferal Mg/Ca record, derived from *C. wuellerstorfi* and *O. umbonatus*, converted to bottom water temperature (BWT) using the equation: $\text{Mg/Ca} = 0.15 \text{ BWT} + 1.16$; (c) seawater ($\delta^{18}\text{O}_{\text{sw}}$ in ‰SMOW) and sea level estimates (green line represents three-point smoothed curve) derived from the Mg/Ca-BWT and $\delta^{18}\text{O}_b$ records. MPT and LPT refer to mid-Pleistocene and late Pliocene transitions. Black lines represent average signals for each variable determined by applying a Gaussian filter with a cut-off frequency of 400 ka. Modified from Sosdian S and Rosenthal Y (2009) Deep sea temperature and ice volume changes across the Pliocene–Pleistocene climate transitions. *Science*, 325: 306–310.

Figure 3 Various Mg/Ca–temperature calibrations for adult shells of genus *Krithe*. Regression lines are based on samples from (1) Atlantic and central Pacific core tops; (2) data from regression 1 and core tops from Chilean Fjords; (3) same as 2 with Arctic core tops between 0 and 900 m; (4) same as 3 with Arctic core tops deeper than 900 m. Modified from Dwyer GS, Cronin TM, and Baker PA (2002) Trace elements in marine ostracodes. *The Ostracoda: Applications in Quaternary Research*, pp. 205–224. American Geophysical Union.

Significant differences between the two ostracode genera and ontogenic effects within each genus can be minimized by only studying tests of the adult stage for a particular genus (Dwyer et al., 2002). The offsets among the different calibrations suggest that secondary, nontemperature parameters might influence the Mg/Ca record of marine ostracodes. Culture studies show no discernible salinity effects, and dissolution experiments suggest that the effects of postdepositional dissolution on the test composition are minimal (Dwyer et al., 2002). A $\Delta[\text{CO}_3]$ effect on Mg/Ca in ostracodes, which has not yet been fully investigated, might explain the divergence among the calibrations.

Coralline Sr/Ca Paleothermometry

Temperature Calibrations of Sr/Ca in Corals

The variability of skeletal Sr/Ca in hermatypic coral skeletons has been shown in many studies to be highly correlated with monthly or seasonal variations in water temperature. Early studies indicated that the Sr/Ca in coral skeletal aragonite is primarily regulated by water temperature (Beck et al., 1992) with more Sr incorporated in coral skeleton at lower temperatures, as discussed above. The relationship obtained in these studies is of the form:

$$(\text{Sr/Ca})_{\text{coral}} (\text{mmol mol}^{-1}) = B + A(\text{SST})$$

where SST is given in $^{\circ}\text{C}$, and the slope $A = -0.062 \text{ mmol mol}^{-1} ^{\circ}\text{C}^{-1}$ (Beck et al., 1992). These initial observations are supported by more recent studies showing strong correlations between near-monthly coral Sr/Ca and surface water temperature (e.g., Alibert and McCulloch, 1997; DeLong et al., 2007; Goodkin et al., 2007; Linsley et al., 2000, 2004; Marshall and McCulloch, 2002; Nurhati et al., 2009; Wu, 2010) (Figure 4). Generally, the slope of the Sr/Ca–SST relationship is similar for near-monthly coral Sr/Ca and monthly SST (Table 3). Despite the success of the coral Sr/Ca paleo-thermometer at many sites, these and other studies have also revealed potential complicating factors that can limit

the use of this tracer. Some of these factors—uncertainties are summarized below.

Secondary Nontemperature Effects

Disequilibrium offset

In *Porites* corals, although the slope of the Sr/Ca–temperature relationships derived at different sites with different individual corals is generally the same, the intercepts of the linear relationship can be significantly different among sites, even for coral analyzed on the same type of instrument. Marshall and Marshall and McCulloch (2002), working with *Porites* corals from the Great Barrier Reef, attribute this effect to be due in part to the disequilibrium Sr/Ca offset in corals. Similar to the $^{18}\text{O}/^{16}\text{O}$ in corals, the skeletal Sr/Ca is out of equilibrium with seawater Sr/Ca.

Using three intracolony and three intercolony *Porites* coral records from the reefs offshore of Amédée Island, New Caledonia, DeLong et al. (2007) found the coral Sr/Ca signal over the twentieth century to be highly reproducible. They report that the average absolute offset between coeval monthly Sr/Ca determinations between any two coral time series is $0.035 \pm 0.026 \text{ mmol mol}^{-1}$ ($\sim 0.65 ^{\circ}\text{C}$), which is less than twice the analytical precision of the coral Sr/Ca measurements.

At Clipperton Atoll (10°N , 109°W) in the eastern Pacific, Wu (2010) and (Wu et al. (in review) observed an offset in mean Sr/Ca value (mmol mol^{-1}) between three *Porites lobata* colonies as previously observed in other coral skeletal Sr/Ca records (Bagnato et al., 2004; De Villiers et al., 1995; DeLong et al., 2007; Marshall and McCulloch, 2002). The offsets between the cores ranged from a low of $0.04 \text{ mmol mol}^{-1}$ to a high of $0.09 \text{ mmol mol}^{-1}$, which would equate to a 0.5 – $1.3 ^{\circ}\text{C}$ difference in temperature reconstruction.

In Savusavu Bay on Fiji's north island of Vanua Levu ($16^{\circ}49'\text{S}$, $179^{\circ}10'\text{E}$), Wu (2010) observed mean Sr/Ca offset of $0.37 \text{ mmol mol}^{-1}$ between the two adjacent Fiji *Porites* colonies in the same water depth. The colonies are thought to be the same species, based on morphology and skeletal architecture. It is worth noting that the two coral cores were analyzed

Figure 4 Comparison of monthly sea surface temperature (red) for the latitude–longitude grid including Rarotonga in the South Pacific (1° by 1° ; centered at 22° S, 160° W) and Sr/Ca measurements (black) analyzed at 1 mm intervals in a *Porites lutea* coral core from Rarotonga. The x-ray positive of the coral core shows the sampling track and annual growth density bands.

on exactly the same ICP-OES instrument in two different laboratories, following interlaboratory calibration (Harvard and Lamont Doherty). This large offset would equate to an unrealistic temperature reconstruction difference of 10°C based on the Sr/Ca–SST calibration derived in this study, or $\sim 6^\circ\text{C}$

based on the commonly accepted Sr/Ca–SST calibration of $-0.06 \text{ mmol mol}^{-1} ^\circ\text{C}^{-1}$.

The different intercepts for coral Sr/Ca–SST relationships shown in Table 3 reflect the fact that the disequilibrium offset can vary between corals of the same species, even in close

proximity. For the genus *Porites*, the similarity of the slopes of the Sr/Ca–SST relationships (Table 3) indicates that Sr/Ca can be used to accurately reconstruct paleo-water temperature, as long as adequate site- and coral-specific temperature calibrations are carried out. For fossil corals lacking a site-specific calibration, the consistent Sr/Ca–SST slope, but potentially different intercept implies that only relative changes in SST over time can accurately be reconstructed ($\pm 0.5^\circ\text{C}$). In all cases, however, for an individual coral Sr/Ca record to be an absolute temperature proxy, the degree of disequilibrium offset must be constant in that coral. This is generally the case for corals sampled along the maximum growth axis (e.g., DeLong et al., 2007; Wu, 2010).

Many other studies report no or insignificant Sr/Ca offsets from corals at the same or closely adjacent sites. For example, in the Line Islands, Nurhati et al. (2009) found insignificant Sr/Ca offsets between *Porites* corals from Christmas, Fanning, and Palmyra Atolls when measured in the same laboratory. They report correlation coefficients (*r*-values) between SST and monthly Sr/Ca of -0.80 , -0.79 , and -0.71 for Christmas, Fanning, and Palmyra, respectively.

Extension rate

Some studies of slow growing corals have reported growth rate effects on skeletal Sr/Ca. De Villiers et al. (1994) reported significantly higher Sr/Ca ratios associated with slower skeletal extension rates in *Pavona clavus*. De Villiers et al. (1994) argued that the difference between skeleton accretion at 12 and 6 mm year⁻¹ is equivalent to $1\text{--}2^\circ\text{C}$ based on near-monthly calibration with monthly SST. However, Marshall and McCulloch (2002) noted that because De Villiers et al. (1994) did not sample exclusively along the coral's maximum growth axis, this invalidates their calcification rate argument, since it is widely known that sampling in off-axis sections of hermatypic coral skeletons generally yields higher Sr/Ca ratios, apparently due to smaller polyp size and lower skeletal density. In other slow growing corals, Bagnato et al. (2004) and Goodkin et al. (2007) both found strong correlations between Sr/Ca and SST in the slow growing corals *Diploastrea* and *Diploria*, respectively. Goodkin et al. (2007) also observed a skeletal extension rate correlation and developed a correction method for adjusted time series Sr/Ca for extension rate effects.

In faster growing *Porites* corals, Shen et al. (1996) and Alibert and McCulloch (1997) find little growth rate effect on Sr/Ca in *Porites lutea* skeletons accreted in the maximum growth axis and Shen et al. (1996) found no perceptible growth rate effect in *Porites* at accretion rates between 18 and 23 mm year⁻¹. DeLong et al. (2007) analyzed Sr/Ca along several *Porites* cores and slabs from New Caledonia *Porites* and found excellent replication and no apparent skeletal extension rate effects. Wu (2010) measured 5-year average extension and calcification rates on *Porites* cores from Fiji, Tonga, and Clipperton. The results revealed no clear and consistent growth trends and no obvious growth effects on the geochemical proxies $\delta^{18}\text{O}$, $\delta^{13}\text{C}$, and Sr/Ca.

Monthly Sr/Ca oscillations in coral aragonite

Using high spatial resolution ion microprobe analyses, Meibom et al. (2003) have found distinct near-monthly oscillations of *Porites lutea* skeletal Sr/Ca with an amplitude greater

than 10%. They propose that these 'monthly' Sr/Ca oscillations result from metabolic changes that are synchronous with the lunar cycle. As has been previously observed in *Porites* (Cohen et al., 2001), their study show that temporally equivalent skeletal elements in *Porites* can have different Sr/Ca ratios. Some of the skeletal Sr/Ca heterogeneity is apparently due to the presence of night-time and day-time deposited skeletal elements (Cohen et al., 2001). During the night, small micron-sized crystals are deposited at the axial spines of the corallites (centers of calcification). Larger needle shaped crystals are formed during the day along all surfaces of the precipitating skeleton. Microprobe analyses of Sr/Ca show that the night-time and day-time skeletons have significantly different Sr/Ca ratios (e.g., Cohen et al., 2001) and that Sr incorporation into the skeleton may be inversely related to calcification rate (Ferrier-Pages et al., 2003).

Replication of decadal and long-term secular variability in coral Sr/Ca

One means of potentially separating climate-related Sr/Ca variability from variability induced by biologic or diagenetic processes is to develop replicated coral Sr/Ca series from a specific site or in a specific region. Only limited replication of century-scale and decadal Sr/Ca variability has been completed to date, and more replicated multicentury Sr/Ca corals records are needed to assess potential biologic or diagenetic effects on Sr/Ca.

From the South Pacific, Linsley et al. (2006) present partially replicated annually averaged multicentury long *Porites* Sr/Ca series from Fiji and Rarotonga. In this study, Linsley et al. (2006) reported that application of the slope of Sr/Ca–SST relationship derived from near-monthly coral Sr/Ca and monthly SST over a calibration interval from 1970 to the core tops to the entire annually averaged multicentury Sr/Ca series at both sites results in unrealistically large amplitude long-term secular trends in SST. To get the Sr/Ca secular trend and interdecadal amplitude at Fiji and Rarotonga to fit the amplitude of instrumental SST and night time marine air temperature variability from 1870 to 1997 required a scaling of $\sim 0.2 \text{ mmol} \cdot \text{mol}^{-1} \cdot ^\circ\text{C}^{-1}$ whereas the monthly calibrations are 0.053 and 0.065 $\text{mmol} \cdot \text{mol}^{-1} \cdot ^\circ\text{C}^{-1}$ at Fiji and Rarotonga, respectively. This 0.2 $\text{mmol} \cdot \text{mol}^{-1} \cdot ^\circ\text{C}^{-1}$ scaling also resulted in a more realistic amplitude of estimated SST changes before 1870. At Fiji, Sr/Ca results for the 20-year period centered on 1660 would indicate a $4\text{--}5^\circ\text{C}$ cooling relative to the late twentieth century using the calibration derived from comparison to monthly instrumental SST (Linsley et al., 2004). The apparent amplification of inferred SST changes from coral Sr/Ca prior to the calibration period was previously discussed with respect to interdecadal variability in Sr/Ca from both Fiji and Rarotonga by Linsley et al. (2004) and may suggest that at these sites the Sr/Ca–SST relationship has not been constant over the last 380 years.

Replicated monthly resolution Sr/Ca time series from three *P. lobata* coral colonies at Clipperton Atoll ($10^\circ 18' \text{N}$, $109^\circ 13' \text{W}$) in the eastern Pacific are used to assess the fidelity of coral Sr/Ca as a SST proxy in this region of relatively stable SST (Wu, 2010; Wu et al., in review). Significant correlations were found between individual cores and gridded instrumental SST for the calibration period (1981–94) with the three-core average increasing the correlation to SST. Down-core, the

intercolony monthly Sr/Ca records showed good coherence with the exception of a 12-year section of growth in one colony. Although, Wu (2010) could find no evidence of diagenesis or other significant skeletal alterations in this section, the presence of this 'anomalous' interval serves to support the multicoral replication approach. Since AD ~1900, there is an observed secular warming trend of ~1 °C recorded in the coral Sr/Ca records which is 0.5–0.75 °C greater than the trend in instrumental SST. The decadal Sr/Ca variability is also greater than that observed in instrumental SST. The magnitude of these coral Sr/Ca–SST trends are in line with other coral Sr/Ca reconstructions and further supports the conclusion that decadal and secular trends in SST at shallow reef sites are not fully reflected in gridded SST products.

A similar amplification also appears in the results of a digenetically altered coral from Ningaloo reef in Western Australia reported by Müller et al. (2001). However, in New Caledonia *Porites*, it is noteworthy that a network of coral Sr/Ca records shows no apparent amplification of the long-term secular SST signal (DeLong et al., 2007).

Coral Sr/Ca Summary

Coral skeletal Sr/Ca seasonal variability has proven to be highly correlated with monthly instrumental water temperature at many sites and appears to be a potentially useful tracer in paleoceanographic studies. As noted above, the results of several studies have raised questions/concerns about the accuracy of the coral Sr/Ca thermometer in some modern corals that are important since these issues may directly affect interpretation of Sr/Ca data from fossil corals and reports of significant tropical Pacific and Caribbean cooling prior to 10000 years BP (e.g., Beck et al., 1997; Guilderson et al., 1994). Although this tracer clearly has the potential to greatly improve our understanding of oceanic conditions, there remains important work to be done to more fully understand the significance of all modes of Sr/Ca variability in corals.

Magnetic Proxies and Susceptibility

Introduction: Magnetic Susceptibility and Environmental Magnetism in Paleoceanography

Magnetic susceptibility (MS) is one of the most commonly employed proxies in paleoresearch and is routinely measured on materials collected by the Integrated Ocean Drilling Program (IODP, www.iodp.org) and international piston coring cruises. MS measurements are not restricted to the marine realm and are commonly employed in terrestrial drilling programs like the Antarctic Geological Drilling Program (Andrill, www.andrill.org) and the International Continental Drilling Program (ICDP, www.icdp-online.org), as well as many lake coring, terrestrial stratigraphic, Quaternary geological, and archaeological projects. The widespread use of MS reflects its sensitivity as an indicator of lithologic variation, coupled with the practicality and versatility of measurement. MS measurements can be made on many types of samples, from sediment cores and boreholes to discrete samples of any shape or even directly on an outcrop. Setup costs are low and running costs are negligible, data acquisition is fast, sample preparation is minimal, and as it is both nondestructive and does not interfere with other measurements, it is often the first measurement made in many studies. These factors make MS uniquely applicable to a host of problems, yet MS is still poorly understood by many in the Quaternary and geological communities. Even for those who specialize in magnetism, determining what exactly drives MS variations within any particular record is a nontrivial undertaking. MS is just the simplest of many measurements that make up the tool kit known as environmental magnetism (Thompson and Oldfield, 1986) and often many other magnetic measurements are needed to truly understand what drives MS changes (e.g., Table 1). Here we review and assess both the potential and the opportunities MS and environmental magnetism have for deciphering the Quaternary paleoceanographic record.

What Is MS?

All substances respond to a magnetic field, the question is by how much and in what direction. MS is the relationship between an induced magnetization (M) to an applied magnetic field (H), or simply how magnetizable a material becomes when placed in an external magnetic field.

Low-field (~ 0.1 mT) volumetric MS (κ) is the type typically measured in most paleostudies:

$$\kappa = M/H$$

where M is the magnetic moment induced per unit volume (amperes per meter; Am^{-1}) and H is the applied field (Am^{-1}). As both M and H have the same système international d'unités (SI) units, κ is dimensionless. Centimeter–gram–second (cgs) units are also dimensionless, where 4π SI = 1 cgs. Unfortunately, it is often not explicitly stated which system is used in

many MS studies, making comparisons difficult. To exclude density-related effects and permit comparison between diverse samples, volumetric susceptibility can be density-corrected to produce mass-normalized MS values (χ).

$$\chi = \kappa/\rho$$

where ρ is the sample density. SI units of χ are $\text{m}^3 \text{kg}^{-1}$; cgs units are $\text{emu Oe}^{-1} \text{g}^{-1}$.

Influences on MS Values

Different materials, their concentration, and their magnetic grain size and shape, can all affect the MS values of any sample. Resulting from the orbital and spin motions of electrons and their interactions, all materials produce a magnetic response when exposed to a magnetic field, though the nature and strength of this response varies between materials. In the transition metals (Fe, Co, Ni), and their compounds, the magnetization can be particularly strong with parallel (but unequal) coupling of unpaired electrons within a crystal lattice producing a strong magnetization and ferromagnetic or ferrimagnetic behavior (Figure 1; Table 2). True ferromagnetism only exists in the elemental state of these transition metals. As these elements are commonly oxidized (or reduced) into various ferrimagnetic forms in the environment, ferromagnetic behavior is extremely rare in natural samples. Common ferrimagnetic minerals include magnetite, maghemite, and greigite (Table 2). These possess strong positive magnetic susceptibilities and, when present, these minerals will often dominate the MS signal (Figure 1). When atomic arrangements are equal, but opposite, there is no (theoretical) net magnetization as parallel pairings cancel out (antiferromagnetism). However, for a variety of reasons, alignment may not be perfectly parallel in antiferromagnetic minerals and a residual magnetization may result, inducing canted antiferromagnetic behavior (Figure 1). Hematite and goethite are common canted antiferromagnetic minerals possessing weak positive susceptibility (Figure 1; Table 2). Paramagnetic and diamagnetic behavior (Figure 1; Table 2) is induced in samples that have some or no unpaired electrons, respectively. Unlike ferro/ferrimagnetic and canted antiferromagnetic behavior, any induced magnetization in a paramagnetic or diamagnetic material is nonpermanent and lost upon removal of the field. Common examples of paramagnetic magnetic materials are ilmenite, biotite, lepidocrocite, siderite, and pyrite, all exhibiting weakly positive magnetic susceptibilities. Common diamagnetic materials include quartz, calcite, and water with weakly negative magnetic susceptibilities (Figure 1; Table 2). In the absence of ferrimagnetic minerals, paramagnetic or diamagnetic minerals may drive the MS signal.

In many environments, the concentration and type of magnetic minerals are often the dominant controls on MS.

Table 1 Some common magnetic parameters and the discrimination they afford

Parameter	Notes
κ, χ	Magnetic susceptibility (MS): the ratio of magnetization induced to the intensity of the magnetizing field. Measured within a small (~ 0.1 mT) reversible magnetic field either volumetrically (κ) or on a mass-normalized basis (χ). Roughly proportional to the concentration of ferrimagnetic minerals within a sample Units: κ (dimensionless), χ ($\text{m}^3 \text{kg}^{-1}$)
χ_{fd}	Frequency-dependent susceptibility: variation of MS with frequency. Measured at 0.46 and 4.6 kHz on a Bartington MS2B. Indicative of superparamagnetic (SP) grains around the SP/single domain (SD) boundary ($\sim 0.03 \mu\text{m}$). At higher frequencies (χ_{hf}), grains at the SP/SD boundary respond as SD grains; thus, high frequency MS is proportionally lower than low frequency (χ_{lf}) MS Units: expressed as a % of χ_{lf}
ARM	Anhyseretic remanent magnetization: acquired when a sample is placed in a decreasing alternating magnetic field (e.g., 100 mT) in the presence of a small steady biasing field (e.g., 0.1 mT). Sensitive to both ferrimagnetic concentration and ferrimagnetic grain size Units: $\text{Am}^2 \text{kg}^{-1}$
(S)IRM	(Saturation) isothermal remanent magnetization (SIRM): magnetic remanence induced in a sample upon removal of the field. Usually attained in increasing field strengths (e.g., IRM 20 mT, IRM 100 mT) up to the saturating field (SIRM), which is usually an arbitrary term for largest field generated in the laboratory (~ 1000 mT). SIRM is an indicator for the concentration of magnetic minerals but also responds to grain size variations Units: $\text{Am}^2 \text{kg}^{-1}$
SIRM/ χ	This ratio can be diagnostic of either mineralogy, or if mineral type and concentrations are similar, magnetic grain size Units: Am^{-1}
ARM/ χ	This ratio is dominantly used to determine magnetic grain size variations, but it is also somewhat sensitive to concentration Units: Am^{-1}
IRM $\times$ mT/SIRM	Ratio of remanence acquired in a smaller field than SIRM to the SIRM. Different field sizes can reveal different aspects of the magnetic signal independent of magnetic concentration. For example, low fields such as 20 mT are sensitive to coarse-grained magnetite, whereas acquisition at higher fields (e.g., 300 mT) can indicate hematite contributions Units: dimensionless
(Bo)cr SIRM- $\times$ mT/ SIRM S-ratio	Demagnetization parameters: obtained by applying reversed magnetic fields to a previously saturated sample. The coercivity of remanence (Bo)cr is the reverse field (mT) at which the SIRM returns to zero. Loss in other fields SIRM- $\times$ mT/SIRM can be expressed as a ratio. Loss at a field of 100 mT (which discriminates between ferrimagnetic and canted antiferromagnetic minerals) has been termed the S-ratio Units: (Bo)cr (mT), SIRM- $\times$ mT/SIRM, and the S-ratio are dimensionless

However, magnetic grain size and shape may also influence the MS signal. Ferrimagnetic grains organize their magnetization into different regions, or domains, to achieve minimum energy states; this results in a grain size dependence of MS values. For example, in magnetite ultrafine particles known as superparamagnetic (SP) grains ($<0.03 \mu\text{m}$) and larger particles known as multidomain (MD) grains ($>\sim 10 \mu\text{m}$) possess higher MS values than smaller single domain (SD) and pseudo SD (PSD) grains in the 0.03 to $\sim 10 \mu\text{m}$ size range (Figure 2). Anisotropy also affects MS values as not all grains are spherical. Magnetic energies favor ordering along the easiest direction, the long axis of elongate grains, with grain shape having as much as a factor of 2 influence on MS. For more information on the factors affecting MS measurement, see Thompson and Oldfield (1986), Dearing (1999), Evans and Heller (2003), and Tauxe (2010).

MS Measurement

MS is the ratio of the induced magnetic moment to the applied field. Changes to the strength and frequency of the applied field and the temperature at which it is measured induce non-linear magnetic responses in a sample. These differences can provide information about the composition of the materials carrying the magnetization, which is important for their interpretation.

Most common measurements of MS are made in low fields (~ 0.1 mT), which do not permanently magnetize the sample, allowing them to return to their original magnetic state on removal of the field. When ferrimagnetic minerals dominate the mineral assemblage, low-field MS is often assumed to be proportional to their concentration. In greater field strengths, a variety of different minerals and magnetic grain sizes can contribute to the MS signal. However, above a certain critical field, the induced magnetization becomes nonreversible and a magnetization, or remanence, is retained by the sample. Measurement of the magnetization in different field sizes permits construction of remanence parameters and ratios (when measured in zero field) (i.e., isothermal remanent magnetization (IRM; Table 1)) and construction of hysteresis loops (when measured in field) that can be diagnostic of magnetic mineralogy and/or magnetic grain size. MS is dependent on the frequency of the applied field, which has some magnetic grain size dependence. Many systems allow measurements to be made at variable frequencies providing information on the proportion of ultrafine SP grains. MS also displays strong temperature dependence, which is a function of intrinsic magnetic mineralogical properties. Regular measurements made through warming or cooling cycles can produce characteristic curves indicative of different magnetic mineral or grain size populations. In summary, MS is an aggregated function of magnetic concentration, mineralogy, and grain size and

Figure 1 Schematic diagram illustrating the relative strengths and organizations for a range of magnetic behaviors. Adapted from Dearing J (1999) Magnetic susceptibility. shape that is dependent upon the applied field, frequency, and temperature of measurement.

MS Measurement Systems

MS (κ or χ) can be measured on a variety of field and laboratory equipment providing MS measurements of discrete

samples, whole cores, split cores, u-channels, or *in situ* field samples, and can be made in varying field strengths, frequencies, and at different temperatures. For all systems, the magnetic susceptibility produces a magnetic field that induces and measures an infield magnetic moment in response to these three factors.

Due to cost, ease of use, and versatility, the Bartington MS2 is often the most widely available and used MS measurement

Table 2 Magnetic behavior, crystal arrangement and example minerals and mass normalized susceptibilities. Adapted from Dearing J (1999) Magnetic susceptibility. In: Walden J, Oldfield F, and Smith J (eds.) *Environmental Magnetism: A Practical Guide*, Technical Guide No. 6, pp. 35–62. London: Quaternary Research Association.

Magnetic behavior	Crystal arrangement	Minerals	MS
'True' ferromagnetism	Parallel coupling of all unpaired electrons to the applied field	Fe – iron Co – cobalt Ni – nickel	276 000 204 000 68 850
Antiferromagnetism	In oxides of Fe, Co, and Ni, electron coupling occurs via an intermediate oxygen atom with alternate crystal layers aligning opposite to each other resulting in no net magnetic moment		
Ferrimagnetism	If the magnetic moments of the alternating iron compounds are unequal, then a magnetic moment is created	Fe ₃ O ₄ – magnetite γFe ₂ O ₃ – maghemite Fe ₃ S ₄ – greigite	660 440 170
Canted antiferromagnetism	For various reasons, sublattices in otherwise antiferromagnetic arrangements may not be perfectly aligned and a small residual magnetization exists	αFe ₂ O ₃ – hematite αFeOOH – goethite	~0.7 ~0.4
Paramagnetism	Some unpaired electrons align to an applied field; this magnetization is lost on removal of the field	FeTiO ₃ – ilmenite Mg,Fe,Al silicate – biotite γFeOOH – lepidocrocite FeCO ₃ – siderite FeS ₂ – pyrite	1.7 ~0.5 0.7 1.0 0.3
Diamagnetism	Compounds with no unpaired electrons act to repel the applied field; this magnetization is lost on removal of the field	SiO ₂ – quartz CaCO ₃ – calcite H ₂ O – water	–0.0058 –0.0048 –0.009

Units of mass-normalized magnetic susceptibility (MS) – $10^{-6} \text{ m}^3 \text{ kg}^{-1}$.

Figure 2 Domain-size boundaries and variation in MS as a function of magnetic grain size for magnetite. Domain abbreviations: SP = superparamagnetic, SD = single domain, PSD = pseudo-single domain, MD = multi domain. Data from Maher (1988), Ozdemir and Banerjee (1982) and Dankers (1978).

system. Capable of parts per million (ppm) detection of magnetite, it can be coupled with a variety of sensors to allow initial characterization of the magnetic properties of a sample. These measurements are most commonly made at low field (80 Am^{-1}), low frequency (0.47 kHz), and room temperature.

For example, MS2C loop sensors coupled with measurements of γ -ray porosity, p-wave velocity, and electrical resistivity on multisensor tracks are a standard shipboard measurement on

both coring and drilling operations alike. Standard 1.5-m-long core sections can be characterized in as rapidly as 10 min in some configurations, providing real-time data to aid core correlation, site selection, and for initial sediment interpretation. Such measurements should account for the background MS before and after measurement to help correction for local environment and drift complication. This can be easily corrected for when measuring discrete samples as the background can be recorded after

every measurement. Whole-core- or other long-core-logging measurements at relatively high (e.g., centimeter scale) resolution require many MS measurements between background air measurements. Sensor drift is usually assumed to be linear; however, this may not always be a valid assumption. More accurate measurements of drift can be obtained by measuring background MS mid-logging, though this increases measurement time and introduces the potential for positional errors. Core-logging sensors also integrate data over a stratigraphic interval (e.g., the MS2C loop smoothes over twice its sensor diameter; Dearing, 1999); thus, data are smoothed and edge effects at core ends are introduced. It is theoretically possible to reintroduce resolution and lost edge effect data through deconvolution, though in practice this is almost never employed. However, because these measurements are nondestructive, sections can be relogged, subsampled, and remeasured discretely to provide greater precision, accuracy, and resolution where needed.

Different susceptometers have demonstrated precision; however, little work has been done to calibrate systems to examine data accuracy. Sagnotti et al. (2003) noted that different MS2 systems can underestimate reference samples by up to 15% and that differences between MS2 and Kappabridge systems can range from 2% to 13%. MS2 systems can be susceptible to sample volume and positioning differences between measurements with 1.5% differences between 1 and 7 cc samples of the same material. These factors coupled with simple variances in other factors, for example, changes in room temperature, can introduce measurement error. With these types of measurements becoming increasingly popular, more attention is being focused on these problems and standards and protocols are currently being developed to help address some of these issues, which will permit greater accuracy in comparisons of records across the globe.

Environmental Records of Susceptibility

Compounds of iron comprise roughly 5% of the Earth's crust and are ubiquitous in many environments in a variety of inorganic and bioavailable forms (Table 2); for example, iron oxides can constitute 2–6% of basalts (Thompson and Oldfield, 1986). Iron-bearing minerals are often eroded, transported, and deposited coevally with other minerals, nutrients, or pollutants. Thus, magnetic properties of environmental materials often correlate well with other independently determined properties. In many sedimentary environments, magnetite is the most common ferrimagnetic mineral. Given its strong response to a magnetic field (Table 2), low-field MS is often considered proportional to magnetite concentration (Dearing, 1999). However, although mineral concentration is often considered the principal factor driving MS, this is often not the case and these assumptions are not always valid. Natural samples are rarely unimodally composed and instead are aggregates of varying amounts of different minerals and grain sizes, complicating such a simple interpretation. As magnetic properties are not uniform across magnetic mineralogies or grain sizes, the interpretation of what drives MS variation is often not simply a reflection of ferrimagnetic concentration. Similar values can potentially be driven by different

compositions, for example, the presence of a small amount of magnetite or larger concentrations of hematite. MS can be diluted by diamagnetic minerals (e.g., biogenic carbonates) that are often significant components of ocean sediments. The nature of the magnetic carriers also can affect the MS. For example, authigenic bacterial magnetosomes are composed of SP to SD magnetite, while terrigenous inputs to marine systems are often PSD to MD grain sizes. The interplay of all of these factors can sometimes produce different and unique MS values characteristic of a specific environment or process. However, it is rarely possible to determine the factors driving the MS signal from MS measurements alone; a greater suite of magnetic measurements are normally necessary (e.g., Table 1). Such an evaluation is almost always required, not only to identify the absolute drivers of change, but also to recognize the causes of differences between measurements and to help with the understanding and accounting for the potential processes involved in driving these changes.

However, given the abundance of Fe oxides in the environment, their ability to harmonize with natural processes, and the ability of magnetic measurements to detect subtle changes in concentration, mineralogy, and grain size, links are often drawn between measurements of MS and environmental change in many diverse settings. Lacustrine MS records often show strong linkages to other independent climate proxies, and compared to the deep-sea environment, lake records possess relatively high sedimentation rates, enabling high-resolution reconstructions of climate. However, many of the most climatically sensitive lakes are found in glacially proximal environments and are thus temporally restricted due to their postglacial formation. Similarly, loess records have shown to possess remarkable MS archives of climate changes; however, their formation is quasi-continuous and restricted to certain areas of the globe. In contrast, relatively slow but continuous sedimentation rates in marine records permit the potential for long climate change reconstructions from large areas of the globe.

MS as a Paleocceanographic Proxy

Like all other environmental records of susceptibility, the MS records of marine sediments are an aggregated sum of the interplay of magnetic concentration, magnetic mineralogy, and magnetic grain size. Variations in these properties can be forced by, and often be characteristic of, several different depositional processes and postdepositional (diagenetic) transformations. Depositional processes generally reflect the balance between terrigenous flux, modulated by some combination of surface and bottom currents, eolian transport, ice-rafted and other glacial marine processes, volcanogenic inputs, tectonic and downslope transport, and biogenic preservation. Postdepositional alterations may result in the creation, destruction, and/or transformation of magnetic minerals. All these factors can influence an MS signal and their relative influence can vary both spatially and temporally. Unraveling these often codependent influences is a nontrivial matter, but with careful selection of both site location and time period, coupled with analysis and understanding of the factors driving the MS signal, MS records of ocean sediments can potentially reveal much

about the paleohistory of both oceans and climate. Here we will report some of the important ways MS has been used in the study of paleoceanographic and paleoclimatic records of ocean cores and some of the important factors to consider in their interpretation.

MS as a Proxy for Terrigenous Flux

The delivery and distribution of terrigenous sediments to the world's oceans is subject to a number of complex processes. One of the major factors governing terrigenous sediment concentration in the ocean is the availability and transport of detrital grains. Transport and delivery-related processes can be, and have been, climatically mediated over a range of timescales in response to changes in climatic regimes. In environments with minimal diagenetic transformations, the MS records of ocean cores can simply reflect (and are often assumed to reflect) the composition of the terrigenous material delivered to a site. Given that the production of biogenic materials (e.g., carbonate and silica) can also be climatically dependent, the MS records of many marine sediments often reflect the balance between terrigenous flux and biogenic dilution. Common examples of this type of behavior are found in Pacific, Indian, and Atlantic Oceans.

The MS of ODP sites 721 and 722 in the Arabian Sea strongly correlate with the percentage of terrigenous materials ($r=0.98$; Bloemendal and deMenocal, 1989). Delivery of this terrigenous fraction is linked to eolian transport and monsoon intensity. Spectral analysis of the Arabian Sea MS records and ODP site 661 from the eastern equatorial Atlantic showed strong influence of the 23 and 19 ka precession-related orbital periodicities prior to 2.4 My with a shift to 41 ka periodicities after 2.4 My, possibly reflecting ice sheet effects on monsoon climate or dust source regions (Bloemendal and deMenocal, 1989; Figure 3). Similarly for ODP site 882 in the North Pacific, Maslin et al. (1996) used MS as a proxy for ice-rafted debris (IRD), and showed synchronous changes between IRD, the $\delta^{18}\text{O}$ record, and the biogenic opal record (Figure 4). Despite the different processes responsible for delivering sediment to these two sites, both MS records identify a major climate reorganization 2.4–2.7 Ma, resulting in global changes in terrestrial flux from the continents. It is thought that these shifts are associated with the initiation of northern hemisphere glaciations and the start of the Quaternary. These long records linked to climatically mediated terrestrial fluxes helped establish the links between orbital and climatic forcings of MS records.

Greater sedimentation rates in the North Atlantic, coupled with greater carbonate preservation, have permitted higher resolution studies of individual events, with their chronologies constrained by more accurate dating. Surrounded by a terrestrial regime dominated by the growth and decay of continental-scale ice sheets, bedrock geology composed of both highly magnetic basalts and crystalline basement rocks and weakly magnetic carbonates, and a sediment transport regime dominated by dynamic surface and subsurface circulations, the North Atlantic has proven to be an exceptional archive for MS studies of paleoclimate and paleoceanography.

In the mid-latitude IRD belt (40° and 55° N) of the glacial North Atlantic (Ruddiman, 1977), MS has been widely used to

correlate IRD events between cores, illustrating the basin-wide coherence of the IRD pattern. Through glacial and interglacial cycles, Robinson (1986) showed that MS peaks were driven by fluxes of IRD in the mid-latitude North Atlantic, linked to increased glacial calving. This signal is also mediated by productivity (Figure 5). During glacial periods, increased delivery of IRD is coupled with a reduction in the production of biogenic carbonates resulting in high MS values. During interglacials, decreased delivery of IRD is coupled with increased biogenic production resulting in increased diamagnetic carbonates resulting in low MS values. This flux/dilution relationship results in strongly contrasting MS values on glacial/interglacial timescales that are replicable across large spatial scales. The highest glacial susceptibility peaks are associated with sand layers (>150 μm) deposited during Heinrich events (Bond et al., 1992), providing a diagnostic signature of these canonical Laurentide Ice Sheet discharge events that prominently characterize the glacial North Atlantic (e.g., Bond et al., 1992). MS records south of the glacial polar front in the North Atlantic differ greatly from those within the IRD belt, reflecting the strong melting gradient and IRD-forced nature of MS. Mapping of these spatial MS signatures also permitted reconstruction of iceberg trajectory paths, paleosurface currents, and the migration of the glacial polar front.

From the Southern Ocean, Pugh et al. (2009) show MS records from three cores from the Scotia Sea to be almost identical to the European Project for Ice Coring in Antarctica (EPICA) dust record (Figure 6). Again, glacial periods are characterized by high susceptibility and interglacials with susceptibility minima. However, these records are apparently not driven by IRD, but by dust export from continental landmasses. The processes involved in driving ice rafting in the North Atlantic and dust flux in the Southern Ocean are very different; however, MS records show similar trends. This similarity is forced by shifts in dominant global climatic patterns over glacial/interglacial timescales, which in turn mediates the terrestrial flux and the attendant MS record.

While global climate changes can have a large impact on global sediment flux and the MS record, it is essential to interpret any MS record within the context of its location and processes acting in its formation. For example, Stoner et al. (1995) and Carlson et al. (2008) examined the magnetic and geochemical record of cores from the Eirik Drift in the NE Labrador Sea, southwest of Greenland. Unlike the majority of records from further south in the North Atlantic Basin, glacial terminations and interglacial periods are characterized by higher MS values than glacial periods. During the glacial–interglacial transitions of marine isotope stage (MIS) 2/1 and MIS 6/5, enhanced MS is accompanied by a coarsening of magnetic grain sizes and an increase in Ti/Fe concentrations. Here, minima in IRD (represented by the >125 μm fraction) and increases in the silt fraction are synchronous with increases in MS and magnetic grain sizes and are thought to be associated with sediment-laden melt water pulses associated with increased melting of the Greenland Ice Sheet during deglaciation (Carlson et al., 2008; Stoner et al., 1995). Thus, while these Greenland proximal records, like the North Atlantic IRD and Southern and Indian Ocean eolian records are driven by flux of terrigenous fragments responding to changing climate drivers, their MS signals produce very different temporal signatures.

MS records driven by the flux of terrestrial fragments can yield high-resolution information about changes in climate and its effect on the terrestrial landscape. The glacial/interglacial, flux/dilution relationship in the ocean remains a major driver behind many MS records and permits comparisons over local, regional, and to some degree even global scales. However, these records must first be interpreted within the context of the processes driving these records and other factors which may potentially modify this relationship must also be assessed.

MS as a Proxy for Sediment Redistribution

In the deep ocean, MS records often correlate well with IRD percentage and reflect surface currents and iceberg melt routes. However, [Rasmussen et al. \(1997\)](#) showed a remarkable similarity between the MS record of ENAM93-21 from the Faeroe-

Shetland Channel in the North Atlantic and the $\delta^{18}\text{O}$ of the Greenland Ice Core Project (GRIP) record ([Figure 7](#)). This MS record captured all 15 Dansgaard-Oeschger (D-O) cycles within the MIS 3 and MIS 2 intervals. In contrast to the North Atlantic IRD pattern, abrupt warming is characterized by sharp increases in MS, with gradual cooling associated with decreasing MS values, showing little relation to IRD inputs ([Figure 7\(c\)](#)) either in the model proposed by [Robinson \(1986\)](#) or regionally. MS lows are associated with colder stadial periods and Heinrich event intervals. Subsequent studies have found similar patterns along the path of dense overflow waters in the subarctic basins of the North Atlantic that contribute to North Atlantic Deep Water (NADW). Because these overflow waters have been implicated as drivers of the D-O cycles observed in the Greenland ice cores, these MS observations have implications for examination of the processes involved. MS patterns were shown to be strongly controlled by variations

Figure 7 Comparison of (a) $\delta^{18}\text{O}$ from ODP site 609, (b) $\delta^{18}\text{O}$, (c) IRD grains $>500\ \mu\text{m}$, (d) MS from ENAM 93-21, and (e) $\delta^{18}\text{O}$ from the GRIP ice core record. Reprinted from *Quaternary Science Reviews*, 16, Rasmussen TL, van Weering TCE, and Labeyrie L, Climatic instability, ice sheets and ocean dynamics at high northern latitudes during the last glacial period (58–10 ka BP), 71–80, Copyright (1997), with permission from Elsevier.

in titanomagnetite concentration (Kissel et al., 1997; Snowball and Moros, 2003) and similar patterns were shown to be spatially replicable over a transect of several cores (e.g., Kissel, et al., 2009). It is suggested that during colder phases when NADW formation was sluggish, transport and delivery of ferromagnetic magnetite to drift sites was restricted resulting in lower MS values. Conversely, during warmer phases, NADW strength increased, as did basaltic fragment transport, increasing the MS values at these locations.

Peaks and minima of MS in oceanic sediments can often be interpreted in a paleoclimatic context. However, resuspension during downslope turbidite flows and subsequent density-related settling of relatively heavy magnetic minerals within an otherwise magnetically weak matrix can also produce characteristic signatures. These MS peaks can be important for identifying turbidite layers and for distinguishing them from paleosignals, as these events can have severe implications for the paleointerpretation of sedimentary records (e.g. core S8-79-6 in Figure 5). MS peaks generated by these events can often be process and event diagnostic. Goldfinger et al. (2007, 2008) used MS to study paleoseismology, correlating MS peaks between earthquake-event-triggered turbidite flows over several hundred kilometers along the Cascadia margin. Earthquake-generated turbidite deposits have not only been recorded by magnetic measurements on the Pacific margins, but also in Quebec and off the Portuguese Coast, illustrating the potential of MS for identifying these deposits.

MS and Source Variation

IRD, bottom current, and slope process records of MS often assume that magnetic concentration linked to flux/dilution relationships are the principal drivers behind the MS record. However, Pirrung et al. (2002a,b) showed that MS varied over three orders of magnitude in the surface sediments of both the Nordic Seas (Pirrung et al., 2002a) and the Atlantic sector of the Southern Ocean (Pirrung et al., 2002b), linked to the source of minerals from different provinces (Figure 8). Highest values were found around Scoresby Sund and along the Iceland–Faeroe–Shetland Ridge, linked to basaltic sources in the Nordic Seas; similarly, in the Southern Ocean, highest values are proximal to mafic sources. It is often assumed that all ferrimagnetic minerals are terrigenously derived, yet all terrigenous materials are not ferrimagnetic. In the absence of a strong ferrimagnetic source component, MS values may be influenced by weaker magnetic components; such areas are evident, for example, in the Norwegian and western Barents Sea (Figure 8). Variations are evident in other regions of the North Atlantic, with Andrew and Hardardottir (2009) magnetically discriminating between Greenlandic and Icelandic sources on either side of the Denmark Strait. Stoner and Andrews (1999) also showed that sediments sourced from the Hudson Bay ice streams were carbonate-rich and this was reflected in the sediments of the Labrador Sea that possess relatively low MS compared to the rest of the North Atlantic.

Figure 8 MS variation in surface sediments from the Nordic Seas and the Atlantic sector of the Southern Ocean. Reproduced with kind permission from Springer Science+Business Media: *Geo-Marine Letters*, Magnetic susceptibility and ice-rafted debris in surface sediments of the Nordic Seas: Implications for Isotope Stage 3 oscillations, 22, 2002a, 1–11, Pirrung M, Fütterer D, Grobe H, Matthiessen J, and Niessen F, Figure 1; *Geo-Marine Letters*, Magnetic susceptibility and ice-rafted debris in surface sediments of the Atlantic sector of the Southern Ocean, 22, 2002b, 170–180, Pirrung M, Hillenbrand C, Diekmann B, Fütterer D, Grobe H, and Kuhn G, Figure 2.

Heinrich layer MS values are also low in this region, illustrating MS dilution due to diamagnetic carbonate background terrigenous concentrations. Instantaneous tephra deposits can also possess distinct magnetic signatures and can be used as stratigraphic markers (e.g., Peters et al., 2010).

Watkins and Maher (2003) and Watkins et al. (2007) extended the work of Pirrung et al. (2002a) to include both potential sources and core sediments surrounding the whole North Atlantic Basin (Figure 9), both at the present day and during the Last Glacial Maximum (LGM). Their results neatly illustrated that even as sediment from the IRD belt (poleward of 40° N) during the LGM possessed higher susceptibility than present (Watkins et al., 2007), there exists significant regional variation in MS, both for the present day and at the LGM. For example, IRD originating from Icelandic basalts and the North American Shield possess characteristically high susceptibilities, and are reflected in the sedimentary properties of the Western North Atlantic. In contrast, the lower susceptibility areas identified by Pirrung et al. (2002a) are proximal to the gray and red sandstones from Spitsbergen which outcrop and surround the Norwegian and Barents Seas, and eolian dust sources are responsible for the relatively low susceptibility of the central Atlantic. With this variation defined, MS can potentially be used to map the timing and intensity of IRD events,

and under optimal conditions can provide information on their sources through the last glacial–interglacial transition (cf. Watkins and Maher, 2003; Watkins et al., 2007). However, isolating the relative influences of sediment flux and sediment source is an almost impossible process using MS alone. Instead, a wider range of magnetic measurements are often needed (see Table 1), with combinations of these parameters permitting assessment independent of magnetic concentration. Source variation and the roles of IRD and bottom water currents also rarely act in isolation of each other or indeed several other processes which may deliver or restrict transport of terrigenous fractions. Site selection and magnetic measurement which consider these processes, and an interpretation that accounts for them, are often key to successfully relate the MS signal to a certain aspect of the climate system.

Postdepositional Records of MS

Magnetic minerals accumulating in sedimentary environments are often assumed by the paleocommunity to be conservative, maintaining properties that reflect their original source materials and mechanisms of deposition. In areas with high organic matter accumulation and/or in low oxygen environments, organic material may be buried before fully oxidizing, promoting

Figure 9 MS values ($10^{-6} \text{ m}^3 \text{ kg}^{-1}$) of potential sources (bar chart inset) and LGM values of MS for cores covering the North Atlantic (shaded ranges). bacterially mediated reduction diagenesis (Froelich et al., 1979). Fine ferrimagnetic grains (either of biogenic or terrestrial origin) are most susceptible to reduction in a profile undergoing diagenetic changes. This can result in partial loss of the deposited magnetic signal and is therefore a significant issue for interpretation of MS records. Deeper in these records, soluble iron can be reprecipitated as other magnetic phases, including pyrite and greigite, and these minerals have shown to be significant components of oceanic records. These minerals can nucleate around larger surviving ferrimagnetic grains protecting their core (and magnetic signal) from further reduction.

Oceanic areas producing strong diagenetic change are generally restricted to continental margins and/or where sedimentation and organic accumulation rates are high and in areas of upwelling and in partially landlocked basins (e.g., the Mediterranean and the Sea of Japan). Such areas are generally well known and while assessment of diagenetic change cannot be conclusive using MS alone, simple additional diagnostic magnetic measurements can help document evidence for diagenetic change. Distinctive signatures include steep decreases in concentration indicators (e.g., MS) with a parallel coarsening of parameters sensitive to magnetic grain size pointing to the selective loss of finer ferrimagnetic grains. As hematite and

goethite are less affected by suboxic diagenesis, an increase in coercivity may also accompany selective loss of finer grains.

Diagenetic processes usually result in degradation of the depositional signal and the paleoclimatic information it contains. However, reduction-driven diagenetic transformations may not always result from steady-state conditions, but from changing boundary conditions providing additional opportunities for the generation of paleoinformation. For example, in an analysis of four sediment records from the Sea of Japan, light/dark rhythms in the sediment record suggested cyclic switching between times of oxic and anoxic conditions, related to glacio-eustatic sea level changes (Vigliotti, 1997). Here MS correlates with the $\delta^{18}\text{O}$ record, showing sea level-lowered glacial periods are more favorable for production of anoxic basin conditions resulting in an increase in sulfuric compounds and a reduction in magnetic concentration and coarsening of the magnetic grain size. Interglacial periods contain deeper waters, greater basin oxygenation, and greater retention of the fine ferrimagnetic fraction (Figure 10).

Postdepositional transformations act not only to remove ferrimagnetic minerals from a profile, but *in situ* production of fine-grained authigenically derived bacterial magnetite can also potentially significantly alter the depositional record. Bacterial

Figure 10 Sulfur (%) and MS for ODP sites 794 (open symbols) and 795 (full symbols) from the Sea of Japan through 18 marine isotope stages. magnetite chains have been identified as significant remanence carriers in both oxic and anoxic oceanic records (e.g., Kirschvink, 1982; Petersen et al., 1986; Stolz et al., 1990). Mechanisms controlling their formation can also possess certain boundary conditions. Lean and McCave (1998) examined a deep-sea core east of New Zealand, identifying bacterial magnetite phases and proposing climatic mediation of conditions favoring bacterial magnetite formation. However, this record is probably not reflective of all authigenic contributions, especially in areas susceptible to diagenesis. As with fine-grained ferrimagnetic constituents within terrigenous sediment, these phases are rapidly lost as they pass through the upwardly migrating Fe redox boundary by iron-reducing bacteria (Karlin et al., 1987; Robinson et al., 2000). Thus, in general, bacterial magnetosomes typically are only found in the upper few meters of sediment. These organisms produce extracellular SP magnetite, which can be readily distinguished from coarse-grained IRD or high-coercivity eolian dusts by additional magnetic measurements. However, if they go undetected in a sediment record, they have the potential to overprint the depositional magnetic signal which may result in an erroneous interpretation.

Conclusions

The MS record at any one site is the sum of the influences of many factors including flux and subsequent redistribution (by numerous processes, the source and mineralogy of the terrigenous material, and dilution by diamagnetic materials). This signal can then be a modified transformation of the magnetic fraction postdepositionally.

Correlations between MS and other climate proxies result from the ubiquitous nature of iron oxides in marine sedimentary environments and their sensitivity to climatically driven processes. The key is to derive which aspect of the climate system they are recording. Similar records can be produced by very different processes, which can lead to erroneous interpretations. Therefore, independent constraints are required when interpreting MS record beyond the local scale. As similar delivery processes can often produce different MS records or as postdepositional processes can affect records to different degrees, it is often necessary to couple MS measurements with other simple magnetic analyses to understand the drivers of the MS changes before attempts are made to extract any paleoinformation.

In summary, MS measurements have proven to be a highly effective tool for the interpretation of paleoenvironmental change, possessing sensitivity to aspects often unresolvable by other methods. With good understanding of the reasons driving any MS changes, MS records have become part of a two-way iterative feedback process for the understanding of paleoclimate. We have to understand the climatic drivers before we can interpret the MS signal, but the MS record can provide excellent new insights into paleoclimate that may not be available using other proxies. Ongoing work to address issues of inter-lab calibration and recognition of the potential for increased resolution through particle-sized specific measurement will only increase the robustness and understanding of these techniques.

Nutrient Proxies

T M Marchitto, University of Colorado, Boulder, CO, USA

© 2013 Elsevier B.V. All rights reserved.

Introduction

The distribution of marine nutrients in the past is of interest to paleoceanographers for two main reasons. First, nutrients control oceanic primary productivity, which is believed to be an important control on atmospheric CO₂ on glacial–interglacial timescales. Second, nutrients are useful tracers of deep-water masses, and changes in the modes and locations of deep-water formation are believed to have fundamentally influenced Quaternary climates. Reconstruction of paleonutrients relies mainly on five proxies that are recorded in marine sediments: foraminiferal $\delta^{13}\text{C}$, Cd/Ca, Ba/Ca, and Zn/Ca; and organic matter $\delta^{15}\text{N}$.

Carbon-13

Systematics

Dissolved inorganic carbon (DIC), also known as ΣCO_2 , is composed of three dominant species in seawater: dissolved carbon dioxide (CO₂(aq)), bicarbonate (HCO₃[−]), and carbonate (CO₃^{2−}), having relative concentrations on the order of 1%, 90%, and 10%, respectively. Furthermore, carbon has two stable isotopes: ¹²C (98.9%) and ¹³C (1.1%). Fractionation between these two isotopes is expressed in delta notation:

$$\delta^{13}\text{C} = \left[\left(^{13}\text{C}/^{12}\text{C} \right)_{\text{sample}} / \left(^{13}\text{C}/^{12}\text{C} \right)_{\text{standard}} - 1 \right] \times 1000 \quad [1]$$

where the standard is a calcium carbonate, usually referenced to the Pee Dee Belemnite standard. On this scale, the $\delta^{13}\text{C}$ of DIC ranges between about −1‰ and 2.5‰ in the world's oceans (Kroopnick, 1985). Photosynthetic fixation of carbon preferentially utilizes ¹²C such that primary marine organic matter $\delta^{13}\text{C}$ is typically between −20‰ and −30‰. This leaves the remaining surface ocean DIC pool slightly enriched in $\delta^{13}\text{C}$. As organic matter sinks through the water column and decays, its ¹²C-rich carbon is regenerated along with other nutrients such as phosphate and nitrate, resulting in a water column $\delta^{13}\text{C}$ profile that is inversely correlated with these nutrients (Figure 1). If biogeochemical cycling were the only process acting on the DIC pool, $\delta^{13}\text{C}$ would decrease by about 1.1‰ for each 1 μmol kg^{−1} increase in dissolved phosphate, and an oceanic range of about 3.3‰ would be possible (Lynch-Stieglitz et al., 1995). Regional differences in the $\delta^{13}\text{C}$ of marine organic matter may alter the slope of this relationship.

In addition to biogeochemical cycling, the $\delta^{13}\text{C}$ of surface ocean DIC is significantly affected by air–sea exchange of CO₂. If DIC were at isotopic equilibrium with atmospheric CO₂, it would be enriched by about 8‰ relative to the atmosphere at 20 °C. This value results from the dominance of HCO₃[−], which is enriched by 8.5‰ relative to the atmosphere, with smaller contributions from CO₃^{2−} (6‰) and CO₂(aq) (−1‰) (Lynch-Stieglitz et al., 1995). The enrichment for HCO₃[−] (and

therefore DIC) increases by about 0.1‰ per degree of cooling. However, isotopic equilibration between the surface ocean mixed layer and the atmosphere is never reached because the time required (on the order of a decade) is longer than surface ocean mixing times. The extent of equilibration may be increased through longer air–sea contact time or high winds, which would increase DIC $\delta^{13}\text{C}$. A final air–sea effect occurs in areas where there is net movement of CO₂ into or out of the surface ocean. Both CO₂(aq) and atmospheric CO₂ are isotopically light compared to DIC. Regions that absorb CO₂ from the atmosphere, such as the low-*p*CO₂ North Atlantic, therefore experience $\delta^{13}\text{C}$ depletion. Areas that emit CO₂ to the atmosphere, such as the high-*p*CO₂ eastern equatorial Pacific, experience $\delta^{13}\text{C}$ enrichment. The net effect of the various air–sea exchange processes spans a surface ocean range of about 2‰ (Lynch-Stieglitz et al., 1995). In addition, the anthropogenic evolution of atmospheric CO₂ toward lower $\delta^{13}\text{C}$ values, known as the Suess effect, results in a progressive lowering of surface water $\delta^{13}\text{C}$ that has already propagated into the deep North Atlantic (Olsen and Ninnemann, 2010).

Paleoceanographic Reconstruction

Reconstruction of past ocean $\delta^{13}\text{C}$ relies mainly on the calcitic (CaCO₃) tests of protozoa called Foraminifera. Foraminiferal calcite carbon is presumed to be derived from dissolved HCO₃[−], and may therefore be expected to record the $\delta^{13}\text{C}$ of DIC, in the absence of complicating biological effects. Core-top calibrations show that various taxa of benthic Foraminifera faithfully reflect the $\delta^{13}\text{C}$ of bottom water DIC (Duplessy et al., 1984). Epifaunal species are preferred for reconstructions because infaunal taxa record pore water values, which are typically lower than those of bottom waters due to organic matter remineralization (Zahn et al., 1986). However, the $\delta^{13}\text{C}$ of even epifaunal species may be lower than that of bottom waters in regions where organic matter rain rates are very high (Mackensen et al., 1993).

Benthic foraminiferal $\delta^{13}\text{C}$ provides a picture of the past distribution of deep-water masses. Biogeochemical cycling and air–sea exchange cause most surface waters, particularly those stripped of nutrients, to be more enriched in $\delta^{13}\text{C}$ compared to the deep ocean. North Atlantic Deep Water (NADW) is today formed from such low-nutrient waters, and therefore carries a high- $\delta^{13}\text{C}$ signature (Figure 2). In contrast, Antarctic Bottom Water (AABW) and Antarctic Intermediate Water (AAIW) are formed from poorly ventilated surface waters and therefore carry low- $\delta^{13}\text{C}$ signatures. Lowest $\delta^{13}\text{C}$ values are found today in the deep North Pacific, far from the well-ventilated NADW source.

Today NADW transports a large amount of heat into the North Atlantic, and past changes in its formation are believed to have strongly impacted regional climates. The most extensively studied period in this regard is the Last Glacial Maximum

Figure 1 Modern seawater profiles of the main nutrient proxies. (a) $\delta^{13}\text{C}$ of DIC (Kroopnick, 1985) compared to dissolved phosphate (Broecker et al., 1982) in the central North Pacific; (b) Dissolved Cd compared to dissolved phosphate in the eastern North Pacific (Bruland, 1980); (c) Dissolved Ba (Ostlund et al., 1987) compared to total alkalinity (Broecker et al., 1982) in the central North Pacific; (d) Dissolved Zn compared to dissolved silica in the eastern North Pacific (Bruland, 1980); (e) $\delta^{15}\text{N}$ of dissolved nitrate compared to dissolved nitrate in the Indian sector of the Southern Ocean (Sigman et al., 1999).

Figure 2 Meridional section of the $\delta^{13}\text{C}$ of DIC in the western Atlantic Ocean during the 1970s (reproduced from Kroopnick PM (1985) The distribution of ^{13}C of ΣCO_2 in the world oceans. *Deep-Sea Research* 32: 57–84). Major water masses are indicated, and the numbers at the top refer to oceanographic cruise stations. Preindustrial $\delta^{13}\text{C}$ values were slightly higher at the sea surface and in the North Atlantic, shallower than ~ 2 km (Olsen and Ninnemann, 2010).

(LGM, ~ 20 ka BP), for which meridional Atlantic $\delta^{13}\text{C}$ sections have been created. Such reconstructions suggest that low- $\delta^{13}\text{C}$ AABW expanded into the North Atlantic and that its boundary with high- $\delta^{13}\text{C}$ NADW shoaled from a water depth of 4 to ~ 2 –3 km (Figure 3; Curry and Oppo, 2005; Duplessy et al., 1988). This reorganization was long assumed to be due to a reduction in the formation rate of NADW, but other more rate-sensitive proxies have since underscored the fact that paleonutrients constrain only the spatial extent of water masses and not their fluxes. The glacial form of NADW, dubbed Glacial North

Atlantic Intermediate Water (GNAIW), likely formed significantly southward of its modern deep convection regions. This migration may therefore have cooled high latitudes even if formation rates were not reduced. On longer Quaternary time-scales, the $\delta^{13}\text{C}$ gradient between the North Atlantic and Pacific has been used to monitor NADW extent. As during the LGM, NADW volume was apparently reduced during all Northern Hemisphere glaciations.

One interesting aspect of the glacial $\delta^{13}\text{C}$ distribution is that the lowest values occurred in the deep Southern Ocean, rather

Figure 3 Meridional section of benthic foraminiferal $\delta^{13}\text{C}$ for the LGM western Atlantic (Curry and Oppo, 2005). Arrows indicate presumed flow directions of AAIW, GNAIW, and AABW, and small white dots show locations of sediment cores used in the reconstruction.

than in the North Pacific as they do today. Glacial production of a North Pacific Deep Water could explain the pattern, but such a water mass is difficult to document, in part because of the poor preservation of calcite in the North Pacific. Some have attributed low Southern Ocean $\delta^{13}\text{C}$ values to an organic matter microhabitat effect (Mackensen et al., 1993), noting that Cd/Ca (see Section ‘Cadmium’) does not support a very high-nutrient glacial AABW (Boyle, 1992). However, the relative uniformity of glacial $\delta^{13}\text{C}$ in the Atlantic sector of the Southern Ocean suggests that the values are probably reliable (Ninnemann and Charles, 2002). Independent estimates of deep sea salinity and temperature require glacial AABW to have been particularly dense, so perhaps GNAIW avoided extensive mixing in the Southern Ocean en route to the North Pacific, leaving AABW anomalously low in $\delta^{13}\text{C}$. Reduced vertical mixing between these two water masses is supported by an enhanced oxygen isotope vertical gradient in the deep Atlantic (Lund et al., 2011).

The $\delta^{13}\text{C}$ pattern in the glacial Atlantic implies that there was a net shift of DIC from the upper ocean into the deep ocean. A comparable $\delta^{13}\text{C}$ shift has been documented in the glacial Indian Ocean, and although data coverage in the Pacific is comparatively poor, an intermediate- to mid-depth $\delta^{13}\text{C}$ gradient is generally supported (Herguera et al., 2010). Glacial DIC deepening may have acted to lower atmospheric CO_2 , through both the direct effect of decreased surface ocean DIC and the compounding effect of increased oceanic alkalinity due to greater dissolution of seafloor CaCO_3 (Sigman et al., 2010).

Reconstruction of surface water $\delta^{13}\text{C}$ appears to be more complicated than deep-water work because of confounding influences on planktonic foraminiferal $\delta^{13}\text{C}$ (Keigwin and Boyle, 1989; Spero, 1998). For example, culture work shows that photosymbionts, respiration, and carbonate chemistry affect the $\delta^{13}\text{C}$ of various taxa. Nevertheless, planktonic-benthic comparisons may record past shifts of DIC partitioning between the upper and deep oceans, with the implications for atmospheric CO_2 mentioned earlier (Shackleton et al., 1983). A widespread planktonic $\delta^{13}\text{C}$ minimum during the last deglaciation may represent the release of DIC that was

stored in the isotopically light and isolated AABW during glacial times (Spero and Lea, 2002).

On glacial-interglacial timescales, the partitioning of carbon between land and ocean must also be considered. It is estimated from benthic Foraminifera that the average $\delta^{13}\text{C}$ value of the world’s oceans was 0.3‰ lower during the LGM (Duplessy et al., 1988). This estimate is subject to considerable error because of the scarcity of data in some regions, particularly the North Pacific. Assuming an average terrestrial carbon isotopic composition of -25‰ , the glacial lowering could be explained by a transfer of 400–500 Gt (10^{15} g) of carbon from land into the ocean, or about 20% of the terrestrial biomass (Crowley, 1995). Independent reconstructions of the LGM terrestrial biosphere, based on paleoecological data, argue for a greater reduction, by up to two or three times that inferred from mean ocean $\delta^{13}\text{C}$. Factors that might reconcile these disparate estimates include glacial carbon storage on exposed continental shelves or in isotopically light methane hydrates.

Trace Metals: Cadmium, Barium, and Zinc

Numerous dissolved trace elements in the ocean exhibit vertical profiles that resemble those of nutrients. That is, they are at low concentrations in surface waters and at greater concentrations at depth. In some cases, this behavior is linked to the element’s importance as a micronutrient. For example, iron is essential for the synthesis of chlorophyll and various algal proteins and is the limiting nutrient in some regions of the ocean. In other cases, nutrient-like behavior may result simply from adsorption onto particulate organic matter in the photic zone and co-remineralization in the deep sea. Regardless of biogeochemical mechanisms, such elements may be useful as nutrient and water mass tracers. Paleoreconstruction relies on the fact that various elements are incorporated into foraminiferal calcite during precipitation. In particular, divalent cations are believed to substitute for calcium in the calcite crystal matrix. Three divalent trace metals have been developed as paleonutrient tracers: cadmium (Cd), barium (Ba), and zinc (Zn).

Cadmium

Dissolved Cd has an oceanic distribution very similar to that of the major nutrient phosphate (Figure 1). Both are nearly completely removed from most surface waters and regenerated at depth, with an intermediate-depth concentration maximum near 1 km. Cd therefore behaves like a labile (easily remineralized) nutrient, and its concentration increases about fivefold between the deep North Atlantic and North Pacific. Although Cd has been linked to at least one important algal metalloenzyme, it is not clear if this use is sufficient to explain its ocean-wide nutrient-like behavior. The global correlation between Cd and phosphate follows a slight curve that may be explained by preferential uptake of Cd over phosphate by particulate organic matter (Elderfield and Rickaby, 2000).

Benthic foraminiferal Cd/Ca ratios reflect seawater Cd concentrations (Boyle, 1992). The relationship between foraminiferal Cd/Ca and seawater Cd is expressed in terms of the partition coefficient:

$$D_{Cd} = (Cd/Ca)_{\text{foram}} / (Cd/Ca)_{\text{seawater}} \quad [2]$$

Calcareous benthic foraminiferal D_{Cd} varies with water depth, from ~ 1.3 in the upper ocean to 2.9 below 3 km. The aragonitic benthic foraminifer *Hoeglundina elegans* has a D_{Cd} of 1.0, invariant with depth. Calcitic partition coefficients also appear to be reduced in waters that are very undersaturated with respect to calcite, such as in the deep Pacific (McCorkle et al., 1995).

Cd/Ca generally supports $\delta^{13}C$ observations indicating that low-nutrient NADW was less extensive in the glacial Atlantic Ocean and was present as the shallower GNAIW (Figure 4; Boyle and Keigwin, 1987; Marchitto and Broecker, 2006). A notable difference between the two proxies is the already mentioned deep Southern Ocean discrepancy, where glacial $\delta^{13}C$ shows very low values in contrast to Cd/Ca, which is similar to the current value. An undersaturation effect on Cd/Ca and/or a microhabitat effect on $\delta^{13}C$ might explain some of the difference. Alternatively, large-scale changes in deep-water ventilation might have decoupled the two tracers such that AABW was depleted in $\delta^{13}C$ without being significantly enriched in Cd.

The Southern Ocean problem highlights the fact that because $\delta^{13}C$ and Cd behave somewhat differently in the modern ocean, unique information may be derived from paired

measurements that is not available from either tracer alone. Specifically, air–sea exchange affects $\delta^{13}C$ but not Cd, so combining the two can potentially reveal past air–sea processes (Lynch-Stieglitz and Fairbanks, 1994). Paired measurements from various regions of the glacial ocean suggest that different deep-water masses had distinct air–sea signatures, allowing for the separation of biogeochemical aging and water mass mixing. LGM Atlantic observations may be largely explained by mixing between well-ventilated GNAIW and poorly ventilated AABW (Marchitto and Broecker, 2006).

Planktonic Foraminifera incorporate Cd with a similar range of partition coefficients as benthics (Delaney, 1989), but less paleoceanographic work has been done with planktonics. Cd/Ca from a polar species suggests that LGM nutrient levels in the high-latitude North and South Atlantic were not much different from today, arguing against changes in NADW and AABW end member properties as explaining the deep sea record (Keigwin and Boyle, 1989). Temperature appears to affect the incorporation of Cd in at least one planktonic species (Rickaby and Elderfield, 1999), and correction for this influence implies that glacial Southern Ocean surface nutrient levels were elevated south of the modern Polar Front, but relatively unchanged north of it (Elderfield and Rickaby, 2000), seemingly in contradiction with $\delta^{15}N$ data (see Section ‘Nitrate Utilization’).

Barium

Dissolved Ba is moderately depleted in surface waters and reaches maximum concentrations below ~ 2 km (Figure 1). Its distribution resembles that of alkalinity, but the association is coincidental (Lea and Boyle, 1989). Ba is removed from shallow waters mainly by barite formation in decaying organic matter, while alkalinity is removed mainly by $CaCO_3$ formation. Both are regenerated at depth as their carrier phases dissolve, and deep-water masses have characteristic Ba and alkalinity values, with Ba increasing about threefold between the deep North Atlantic and North Pacific. Due to its refractory (less easily remineralized) behavior, Ba may offer information that is distinct from the more labile Cd. Ba is incorporated into several taxa of calcitic benthic Foraminifera with a partition coefficient of ~ 0.4 (Lea and Boyle, 1989), and there is

Figure 4 Meridional section of seawater Cd concentration in the LGM Atlantic, reconstructed from benthic foraminiferal Cd/Ca (Marchitto and Broecker, 2006). Black dots show locations of sediment cores used in the reconstruction.

Figure 5 Records of benthic foraminiferal $\delta^{18}\text{O}$, $\delta^{13}\text{C}$, Cd/Ca, and Ba/Ca in a sediment core from the deep North Atlantic spanning the past 210 ka (Lea and Boyle, 1990a). Low $\delta^{13}\text{C}$ and high Cd/Ca and Ba/Ca generally occur during glacial stages (indicated by high $\delta^{18}\text{O}$ and labeled as marine isotope stages 2, 4, and 6), indicative of high nutrients and the presence of AABW. Note the reversed scales for $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$.

evidence that this value is reduced in strongly undersaturated waters (McCorkle et al., 1995).

For the LGM Atlantic, benthic Ba/Ca supports the view that low-nutrient NADW was replaced by the shallower GNAIW (Figure 5; Lea and Boyle, 1990b). Low intermediate-depth Ba/Ca also appears to rule out the Mediterranean Sea as an important contributor to GNAIW, since water from that basin carries high Ba concentrations. In contrast to $\delta^{13}\text{C}$ and Cd/Ca, however, there was no apparent glacial Ba gradient between the deep Atlantic and the Pacific. Deep ocean Ba may have become decoupled from the other nutrient tracers because of an increase in barite regeneration at the seafloor, possibly associated with increased productivity (Lea and Boyle, 1990b).

Zinc

Dissolved Zn has an oceanic distribution very similar to that of the nutrient silica (Figure 1). Both are nearly completely removed from most surface waters, but unlike the labile Cd and phosphate, they lack intermediate-depth concentration maxima. Zn therefore behaves like a refractory nutrient, with maximum concentrations below $\sim 1\text{--}2$ km water depth. Zn is an essential micronutrient for many marine organisms, second only to iron among the biologically important trace metals. In particular, its use by diatoms (algal protists with siliceous shells) in the enzyme carbonic anhydrase may explain its oceanic association with silica. Zn concentrations increase more than tenfold between the deep North Atlantic and North Pacific, and there is a sevenfold meridional increase within the deep Atlantic alone. Zn/Ca may therefore be a very sensitive tracer of past interactions between NADW and AABW (Marchitto et al., 2002).

At least two species of calcitic benthic Foraminifera incorporate Zn with a partition coefficient that depends strongly on the saturation state. In sufficiently supersaturated waters D_{Zn} is ~ 9 , but it may be as low as ~ 4 in the corrosive deep Pacific. The glacial increase in deep North Atlantic Zn due to the increased presence of AABW was therefore partially muted in Zn/Ca because of AABW's lower saturation state (Marchitto et al., 2002). Nevertheless, paired Zn/Ca and Cd/Ca measurements provide

Figure 6 Difference between LGM and Holocene bulk sediment $\delta^{15}\text{N}$ in the Southern Ocean and Indian Ocean (Francois et al., 1997). Numbers at right show mean values for four regions. There was an increase in $\delta^{15}\text{N}$ south of the modern Polar Front ($\sim 50^\circ\text{S}$) during the LGM, suggesting increased NO_3^- utilization due to reduced nutrient upwelling.

strong evidence for glacial AABW expansion, and not some independent change in NADW nutrient content.

Nitrogen-15

Nitrate Utilization

Along with carbon and phosphate, nitrate (NO_3^-) is an essential major nutrient for marine primary production, and is often the limiting nutrient in the open ocean. Like carbon, nitrogen has two stable isotopes: ^{14}N (99.6%) and ^{15}N (0.4%). Fractionation is again expressed in delta notation:

$$\delta^{15}\text{N} = \left[\left(\frac{^{15}\text{N}}{^{14}\text{N}} \right)_{\text{sample}} / \left(\frac{^{15}\text{N}}{^{14}\text{N}} \right)_{\text{standard}} - 1 \right] \times 1000 \quad [3]$$

where the standard is atmospheric N_2 . Phytoplankton preferentially incorporate the lighter isotope, leading to $\delta^{15}\text{N}$ enrichment of the remaining dissolved NO_3^- pool. In regions where

the NO_3^- supply is heavily utilized, the surface ocean isotopic enrichment can be relatively large (order of 10‰; **Figure 1**), and organic matter $\delta^{15}\text{N}$ increases in parallel. To the first order, the $\delta^{15}\text{N}$ of sedimentary organic matter may therefore be used to reconstruct past surface ocean NO_3^- $\delta^{15}\text{N}$, and thus the degree of NO_3^- utilization (**Altabet and Francois, 1994**). There are indications that sedimentary bulk organic matter $\delta^{15}\text{N}$ may be subject to diagenetic alteration in some environments, which might be avoidable by measuring diatom-bound $\delta^{15}\text{N}$ (**Robinson and Sigman, 2008**).

Past NO_3^- utilization is of particular interest in the Southern Ocean, the largest area of incomplete consumption of NO_3^- and phosphate by phytoplankton in the modern oceans. Here, deep waters charged with nutrients and DIC upwell to the surface, but they are subducted again before their nutrient

load can be efficiently extracted, resulting in a missed opportunity for the ocean's 'biological pump' to sequester CO_2 (**Sigman et al., 2010**). Hypothetically, the resulting leak of CO_2 into the atmosphere could have been stemmed during glacial times either by increased biological productivity or by reduced vertical mixing. Both processes would be recorded as increases in $\delta^{15}\text{N}$ due to a more complete NO_3^- utilization. South of the modern Polar Front, $\delta^{15}\text{N}$ data indeed suggest that NO_3^- utilization was enhanced during the last glaciation (**Figure 6**), and proxy evidence for reduced export production confirms that this change was related to reduced upwelling and/or stronger surface stratification (**Francois et al., 1997; Robinson and Sigman, 2008**). North of the modern Polar Front, export production increased, but NO_3^- utilization apparently did not rise as much as it did south of the front, implying that the

Figure 7 Sedimentary $\delta^{15}\text{N}$ records from off southern Chile (c) (**Robinson et al., 2007**), California (d) (**Hendy et al., 2004**), and Oman (e) (**Altabet et al., 2002**), compared to $\delta^{18}\text{O}$ of ice (a proxy for air temperature) in Greenland (a) and Antarctica (b). Numbers at the top indicate marine isotope stages, and gray bars denote millennial-scale warm events in Antarctica. Also shown (on a reversed scale) is $\delta^{15}\text{N}$ in the subantarctic zone of the Southern Ocean (f). Reproduced from **Robinson RS, Mix A, and Martinez P (2007) Southern Ocean control on the extent of denitrification in the southeast Pacific over the last 70 ka. *Quaternary Science Reviews* 26: 201–212.**

enhanced productivity could have resulted from increased upwelling. It has been suggested that the changes south of the Polar Front had a greater impact on the atmosphere, contributing to glacial CO₂ lowering.

Denitrification

A second important influence on the $\delta^{15}\text{N}$ of dissolved NO₃[−] is water column denitrification, which represents an important loss of fixed nitrogen from the oceans. Under suboxic conditions, NO₃[−] may be used by certain bacteria as an electron acceptor during organic matter degradation, producing N₂O and N₂. Like NO₃[−] utilization, this process preferentially uses ¹⁴N and results in $\delta^{15}\text{N}$ enrichment of the remaining NO₃[−] pool. While well-oxygenated deep waters are typically ~5–6‰ in $\delta^{15}\text{N}$, denitrification may drive the values above 18‰. Today, denitrification occurs primarily in the intermediate-depth oxygen minimum zones (OMZs) of the eastern tropical North and South Pacific, and the Arabian Sea.

Along the western Mexico continental margin, bulk sediment $\delta^{15}\text{N}$ was about 2–3‰ lower during late Quaternary glacial intervals, indicative of reduced denitrification in this region (Ganeshram et al., 2002). Other sediment cores from the eastern tropical North Pacific exhibit reduced organic carbon content and increased bioturbation during glacial times, consistent with erosion of the regional OMZ. Arabian Sea sedimentary $\delta^{15}\text{N}$ was similarly reduced (Altabet et al., 2002), suggesting that global rates of denitrification were significantly lower during glacial periods. This may have resulted in an increased oceanic inventory of NO₃[−], possibly stimulating primary production in oligotrophic (subtropical gyre) regions and contributing to the glacial drawdown of atmospheric CO₂. However, phosphate limitation likely became important, reducing overall NO₃[−] fixation and limiting the biological impact of reduced denitrification (Ganeshram et al., 2002).

OMZ weakening during glacial periods may have resulted from decreased upwelling-driven productivity in those regions, and/or increased ventilation by high-oxygen intermediate waters. In the Arabian Sea, sediment $\delta^{15}\text{N}$ also decreased during millennial-scale intervals corresponding to the Northern Hemisphere cold stages of the last Ice Age, the so-called Dansgaard-Oeschger stadials (Figure 7(a) and (e); Altabet et al., 2002). Reduced denitrification at these times was likely due to reduced summer upwelling and productivity in response to a weakened southwest Indian monsoon. $\delta^{15}\text{N}$ off southern Chile also displayed millennial-scale variability during the last Ice Age, but with a timing that more closely mimics the temperature history of Antarctica (Figure 7(b) and (c); Robinson et al., 2007). $\delta^{15}\text{N}$ records from the eastern North Pacific OMZ appear to transition from Antarctic-like timing near the equator to Greenland-like timing further north (Figure 7(d); Hendy et al., 2004; Robinson et al., 2007; Pichevin et al., 2010), pointing to some combination of southern and northern forcing along this margin. Enhanced ventilation of Subantarctic Mode Water during Antarctic cold phases may have delivered more oxygen to the eastern tropical and South Pacific OMZs, resulting in less denitrification. Furthermore, if enhanced NO₃[−] utilization occurred in the Subantarctic Southern Ocean during cold phases, as suggested

by higher diatom-bound $\delta^{15}\text{N}$ (Figure 7(f); Robinson et al., 2007), then nutrient delivery to the low-latitude world ocean would have been reduced, leading to lower productivity and less demand for oxygen in the regions of the modern OMZs. In contrast to the Southern Ocean, changes in upwelling and productivity above the low-latitude OMZs are believed to exert little leverage on atmospheric CO₂ because nutrients upwelled there are completely utilized eventually (Sigman et al., 2010).

Introduction

The Pleistocene, also known as the 'Ice Ages,' starts 2.6 Ma. At the beginning of the nineteenth century, the first geological evidence of major Quaternary glacial episodes came from observations by Louis Agassiz of sediment deposits (moraines) and erosion features attributed to ancient glaciers in the Jura mountains of Western Europe. Up until about 1960, however, most of the Ice Age puzzle remained unexplained. One theory was very promising in explaining the Ice Ages: the astronomical theory of climate developed by a Serbian professor of mathematics, Milutin Milankovitch. Based on his calculations of seasonal and latitudinal distribution of solar energy at the surface of the Earth, [Milankovitch \(1930\)](#) proposed an orbital theory of Ice Ages in which waxing and waning of continental ice sheets are under the control of long-term, orbitally driven changes in summer insolation over the high latitudes of the Northern Hemisphere. One of the most interesting aspects of this theory was that it made it possible to test predictions about climatic records such as how many ice-age deposits geologists would find, and when these deposits had been formed during the past 650 ka. During a few decades, however, the astronomical theory of climate was largely disputed because discussions were based on fragmentary geological records obtained on land and supported by incomplete, and frequently incorrect, radiometric age data. The key to unravel the mystery of the Ice Ages would come from the oceanic seafloor covered by continuous sedimentary sections that had recorded hundreds of thousands of years of the Earth's climatic and oceanographic evolution.

A new branch of Earth's Sciences emerged in the 1950s – paleoceanography. One of its major tools for reconstructing the climate evolution of the Earth is stable oxygen isotopes measured from the remains of marine calcareous organisms. This tool provides clues about past changes in seawater temperature and seawater isotopic composition, which is controlled by changes in waxing and waning of large continental ice sheets and is, therefore, directly linked to glacial–interglacial history of the Earth. This article presents the major steps in our understanding of oxygen-isotope fluctuations in the ocean and their use for stratigraphic purposes.

Oxygen Stable Isotopes in Marine Carbonate to Remains: A Brief Overview

Oxygen Stable Isotopes and the δ Notation

There are three stable isotopes of oxygen in nature: ^{16}O , ^{17}O , and ^{18}O , with relative natural abundances of 99.76, 0.04, and 0.20%, respectively. Because of the higher abundances and the greater mass difference between ^{16}O and ^{18}O , research on oxygen isotopic ratios deals normally with the $^{18}\text{O}/^{16}\text{O}$ ratio. The ratio of stable isotopes of oxygen in carbonates is analyzed by gas mass spectrometric determination of the mass ratios of

carbon dioxide (CO_2) released during reaction of the sample with a strong acid. This ratio is expressed as a difference with reference to a standard carbon dioxide of known composition. This difference in isotope ratios, known as δ -value and given in percentage, is calculated as follows:

$$\delta^{18}\text{O} = \frac{(^{18}\text{O}/^{16}\text{O} \text{ sample} - ^{18}\text{O}/^{16}\text{O} \text{ standard})}{^{18}\text{O}/^{16}\text{O} \text{ standard}} \times 1000 \quad [1]$$

A sample enriched in ^{18}O relative to the standard will show a positive δ -value (with a corresponding negative value for a sample enriched in ^{16}O relative to the standard). The standard commonly used in carbonates is referred to as Pee Dee belemnite (PDB; a cretaceous belemnite from the Pee Dee formation in North Carolina, United States). This standard is not available any longer; however, various international standards have been run against PDB for comparative purposes. Two standards are commonly used and distributed by the National Institute of Standards and Technology in the United States, and the International Atomic Energy Agency in Vienna. They are NBS-18 (carbonate) and NBS-19 (limestone; [Coplen, 1988, 1994](#)).

Carbonate Fractionation: The Pioneering Work of H. Urey and S. Epstein

Harold Urey, a Nobel laureate at the University of Chicago, pioneered the analysis of stable isotopes of oxygen in carbonates in the late 1940s ([Urey, 1947](#)). Urey and his colleagues had found that the carbonate shells of marine organisms from cold water contained a higher proportion of the heavier ^{18}O isotope than did organisms living in warmer water ([Urey et al., 1948](#)). In the early 1950s, pushing this promising approach a step forward, Samuel Epstein and colleagues looked for empirical calibrations of modern mollusk shell oxygen-isotope ratios relative to seawater temperatures. This calibration exercise made it possible to derive equations that could be used to estimate past temperatures from fossilized biologic carbonate remains ([Epstein et al., 1951, 1953](#)).

$$T = 16.9 - 4.2 \times (\delta^{18}\text{O} \text{ sample} - ^{18}\text{O} \text{ water}) + 0.13 \times (\delta^{18}\text{O} \text{ sample} - ^{18}\text{O} \text{ water})^2 \quad [2]$$

As is readily seen from the above formula, the oxygen-isotope composition of marine carbonate samples ($\delta^{18}\text{O}$ sample) is not only related to the temperature of precipitation (T , in $^{\circ}\text{C}$), but also to the isotopic composition of seawater ($\delta^{18}\text{O}$ water). In 1954, Willi Dansgaard had pointed out that evaporation/precipitation processes might act like distilleries and concentrate particular oxygen isotopes during the water cycle ([Figure 1](#)). More particularly, the isotopic fractionation process related to evaporation withdraws from the oceans more of the lighter ^{16}O isotope, leaving the ocean water enriched in the heavier ^{18}O isotope. As a consequence, it was hypothesized that during glaciation periods, when the glaciers

Figure 1 The hydrological cycle and its influences on the oxygen-isotope ratios. Molecules of water containing the lighter ^{16}O isotope have a higher vapor pressure and these molecules are preferentially enriched in the vapor phase, showing a much smaller $\delta^{18}\text{O}$ ($\gg\delta^{18}\text{O}$) than the ocean waters from which they derive. During precipitation processes, fractionation acts in the opposite way than during evaporation, leaving the remaining water vapor even more depleted in ^{18}O in the clouds. This Rayleigh fractionation process in the clouds explains why the water vapor that ultimately precipitates at low temperature to form the ice caps is extremely depleted in ^{18}O ($\gg\gg\delta^{18}\text{O}$) relative to the ocean water.

expanded, light ^{16}O atoms of oxygen were preferentially extracted from the sea and stored in the ice sheets, leaving the seawater enriched in the heavier ^{18}O isotope. When the glaciers melted, the stored isotopes flooded back into the ocean, returning it to its interglacial composition.

Pleistocene Oxygen-Isotope Stratigraphy: Early Works

Cesare Emiliani, the Father of Marine Isotopic Stratigraphy

The early work of Urey and his colleagues had involved studies of the relation between oxygen isotopes and temperature in recent mollusks. In the 1950s, the Italian–American geologist Cesare Emiliani started the measurements of oxygen isotopes from calcite shells of Foraminifera. The Foraminifera are unicellular organisms floating in the water column (planktonic species) or living on the seafloor (benthic species) whose calcite tests accumulate in oceanic sediments after their death. Analyzing tests of planktonic Foraminifera sampled down the length of several marine sediment cores, Emiliani found a periodic variation in the ratio of $^{18}\text{O}/^{16}\text{O}$, and interpreted these oscillations as related to glacial–interglacial changes (Emiliani, 1955; Figure 2(a)). Before Emiliani’s work, it was thought that there had been only four major glaciations during the Pleistocene. Working on sediments sampled with long piston cores, Emiliani showed that there had been many more, with at least eight glaciations during the late Pleistocene (Emiliani, 1966; Figure 2(b)).

Emiliani proposed a way of numbering the marine oxygen isotopic stages (MISs) observed in his deep-sea records. This numbering scheme is still used today. Starting from the most recent interglacial (warm) period – the Holocene (MIS 1) – Emiliani attributed an odd number to light isotopic stages, whereas the glacial (cold) periods, characterized by heavier $\delta^{18}\text{O}$ values, were given an even number (Figure 2). Later on, more subtle isotopic variations, such as the episodes of the isotopic stage 5, were broken into a–e substages (Shackleton, 1969).

Continental Ice-Sheet Waxing/Waning and the Global $\delta^{18}\text{O}$ Signal

As seen above (eqn [2]), it was known that the $\delta^{18}\text{O}$ measured from biologic marine carbonates reflected two major effects: the temperature of the seawater in which the organisms developed and the volume of continental ice sheets (which would change the isotopic composition of seawater). Cooler temperatures and greater ice volumes both result in more positive $^{18}\text{O}/^{16}\text{O}$ ratios (higher $\delta^{18}\text{O}$). Emiliani estimated that 60% of the variations he observed in deep-sea records were due to the temperature effect, 40% were due to the ice effect. Based on this estimation, he concluded that equatorial and tropical ocean surface temperatures had been several degrees cooler during times of glaciation. However, this conclusion was soon to be challenged.

Sir Nicolas Shackleton, from Cambridge University (United Kingdom), compared the $\delta^{18}\text{O}$ measured in the tests of surface-dwelling Foraminifera to oxygen isotopic ratios obtained, in the same core, from benthic Foraminifera that had lived on the seafloor. If, as Cesare Emiliani had estimated, the ratio of oxygen isotopes in marine fossils is chiefly governed by sea temperature at the glacial–interglacial timescale, the benthic Foraminifera would have shown much smaller deviations than the planktonic Foraminifera since the temperature of the water at the bottom of the ocean would have likely remained unchanged, close to freezing. But Shackleton’s results showed that the two isotopic curves were nearly identical, indicating that the temperature was not the main effect at play and that most of the glacial–interglacial isotopic signal was related to changes of the continental ice-sheet volume, which in turn controlled the $^{18}\text{O}/^{16}\text{O}$ ratio in the ocean. Instead of having recorded major temperature changes, Emiliani’s $\delta^{18}\text{O}$ curve had been mostly an isotopic message from the ancient ice sheets.

The most accurate constraints to estimate the change of seawater $\delta^{18}\text{O}$ between the Last Glacial Maximum (LGM) and the Holocene are provided by the measurements of pore water $\delta^{18}\text{O}$ and by high-resolution records of benthic foraminifer

Figure 2 (a) One of the first Upper Pleistocene, marine oxygen-isotope records obtained from planktonic Foraminifera (*Globigerinoides ruber*) picked along Caribbean core 179–4 (Emiliani, 1955). Emiliani converted the $\delta^{18}\text{O}$ values to sea-surface temperatures (SSTs) assuming that 60% of the oxygen-isotope variance was related to temperature changes and only 40% to glacial–interglacial changes in ice volume. (b) A longer planktonic isotopic record obtained on the Foraminifera species *G. sacculifer* picked from Caribbean core P6304–9. This record shows the eight major glaciation stages from the Upper Pleistocene (Emiliani, 1966). Isotopic stages as defined by Emiliani.

$\delta^{18}\text{O}$ in the high latitudes. They show that the $\delta^{18}\text{O}$ of seawater in the deep ocean during the LGM was $1.05 \pm 0.2\%$ heavier than today (see Duplessy et al. (2002) for a review).

Currents and global thermohaline circulation mix the ocean water in such way that any chemical change in one part of the ocean should be reflected everywhere within a thousand years. Thus, rapidly, it became obvious that isotopic variations could be used as a powerful stratigraphic correlation tool. Further efforts were, therefore, devoted to test the global nature of the isotopic signal and to date the major oscillations first observed by Emiliani.

Developing a Timescale for the Oxygen-Isotope Stratigraphy

Absolute Dating (^{14}C and U/Th on Coral Terraces)

Since massive corals can grow only within a shallow water depth, past coral terraces provide an accurate record of former sea-level changes. A geochemist at Lamont Doherty Observatory (New York, United States), Wallace S. Broecker, dated fossil coral reefs in the Florida Keys and the Bahamas, and showed that the sea reached a high level 120 and 80 ka ago, presumably during periods of warm climate when melted ice sheets had released large amounts of water to the sea. These periods of high sea levels closely correspond to warm periods predicted by the astronomical theory of climates of M. Milankovitch.

Broecker and Van Donk (1970), working on a $\delta^{18}\text{O}$ record from a Caribbean core, concluded that the major cycle in the marine oxygen isotopic records was 100 ka in duration. Moreover, they emphasized on the fact that the isotopic records showed a characteristic sawtooth pattern in which periods of

glacial expansion averaging about 100 ka in length were abruptly terminated by rapid deglaciations. They labeled these ‘terminations’ (episodes of rapid deglaciation) using roman numbers (I, II, III, ...), starting with the most recent termination (I) corresponding to the deglaciation located between the LGM (at about 20 ka) and the Holocene.

Magnetostratigraphy and the ‘Rosetta Stone’ for Quaternary Ice Ages

The dating of long marine sedimentary series was greatly improved by using magnetic stratigraphy, a technique first established in the early 1960s. This approach is based on the fact that the Earth’s magnetic field periodically reversed in the past. By looking at the magnetic signal imprinted into rocks or sediments, the geologist can pinpoint reversals that had been previously accurately dated (i.e., K/Ar or Ar/Ar dating applied to volcanic rock samples). Neil Opdyke applied this magnetostratigraphy approach to cores from the Lamont’s core repository. Core V28–238, retrieved in the eastern equatorial Pacific, was particularly promising, with the first distinct magnetic reversal of the core corresponding to the Brunhes/Matuyama (B/M) reversal that had been previously dated on land at 730 ka by K/Ar method.

The ‘Brunhes–Matuyama’ reversal was found to occur just before MIS 19 (Shackleton and Opdyke, 1973; Figure 3). Assuming a constant age–depth model for the core, it was now possible to assign ages to each isotope stage by interpolation. Stage 5e, the penultimate interglacial period equivalent to the Holocene, came out at an age of 123.5 ka. A timescale was now available for the entire period for which Milankovitch had made his calculations.

Figure 3 The ‘Rosetta Stone’ of the Ice Ages, oxygen-isotope record from core V28-238 tied into the magnetostratigraphic timescale. This work provided the first accurate chronology of late Pleistocene climate. Modified from Shackleton NJ and Opdyke ND (1973) Oxygen isotope and paleomagnetic stratigraphy of equatorial Pacific core V28-238: Oxygen isotope temperatures and ice volumes on a 105 year and 106 year scale. *Quaternary Research* 3: 39–55.

During the decades between the 1930s and the 1960s, the astronomical theory of climate had been largely disputed, with discussion based on fragmentary geological records supported by incomplete and frequently incorrect radiometric age data. From the 1960s onward, the access to continuous and longer oceanic records revealed many more than the initial four glacial periods recognized from the terrestrial records in Europe, and made it possible to date relatively well these periods. These marine records provided a strong support to the astronomical theory of climate. In 1976, Hays and coauthors published a landmark paper in which they convincingly demonstrated that all the orbital frequencies predicted by the astronomical theory of climate could be found through spectral analysis of climate-sensitive indicators from deep-sea records. One important implication of the astronomical ‘pacemaker’ discovery is that the calculation of past insolation cycle variations could be used as the basis for an astronomically derived timescale.

Astronomical Tuning: The SPECMAP Approach

With the convincing validation of the astronomical theory of climate by Hays et al. (1976), several paleoceanographers proposed the development of a high-precision timescale from deep-sea sedimentary records by using orbitally-related oscillations of paleoclimatic proxies as internal ‘pacemakers’ (i.e., Morley and Hays, 1981). The so-called astronomical (or orbital) ‘tuning’ approach for developing timescales rests on the phase locking of orbitally-related oscillations in sedimentary records to primary orbital oscillations calculated by astronomers, namely, the precession of equinoxes (with periods of 19–23 ka) and the obliquity of the Earth’s axis (with a main period of 41 ka).

To get a global, marine stratigraphic framework on which to develop an Upper Pleistocene astronomical timescale, Imbrie et al. (1984) selected five planktonic Foraminifera oxygen isotopic records from low- and mid-latitudes in which globally persistent isotopic excursions could be graphically correlated. As seen above, over the Ice Age glacial–interglacial cycles, global seawater oxygen isotopic excursions recorded in the Foraminifera calcite chiefly reflect the waxing and waning of continental ice sheets, enriched in the light ^{16}O isotope relative to seawater.

An initial, radiometrically controlled age model was developed for each of the five isotopic records, using few stratigraphic levels: core tops (with a zero age); two isotopic events in stage 2 with ^{14}C ages of 18 and 21 ka; the MIS6–MIS5 isotopic stage boundary (termination II), taken at 127 ka; and the Brunhes–Matuyama magnetic reversal (at the base of MIS19), taken at 730 ka. The astronomical tuning procedure applied by Imbrie et al. (1984) iteratively modifies the initial depth–age model to increase the coherency and phase lock between filtered 19–23 ka and 41 ka oscillations of the oxygen isotopic records, on the one hand, and the precession and obliquity components of Earth’s orbital variations, on the other hand. Such an orbital-tuning approach assumes constant phase lags at the primary Milankovitch frequencies between the marine oxygen isotopic variations and Earth’s orbital changes. Those phase lags had been determined in an earlier paper (Imbrie and Imbrie, 1980) by adjusting the parametrization of a nonlinear (exponential) climatic model predicting ice-volume variations so that the model output would match an 130-ka-long isotopic record, radiometrically dated.

The five astronomically dated isotopic records were finally normalized and stacked, and the resulting curve smoothed with a nine-point Gaussian filter to produce a reference stratigraphic record (Figure 4(a)). The rationale for the stacking approach is that global isotopic changes related to ice-sheet waxing/waning would be enhanced in the resulting composite curve, whereas local or regional isotopic variations would tend to cancel out. Stacking is also useful because it results in a set of well-defined isotopic oscillations that can, in principle, be found in all sediment cores. Figure 5 shows the comparison of filtered precession- and obliquity-related oscillations from the stacked, planktonic isotopic record with obliquity (upper panel) and precession (lower panel) orbital oscillations.

Imbrie and coworkers estimated their geological timescale for the Upper Pleistocene to be accurate to within 5 ka (Imbrie et al., 1984). Since its publication, this orbitally aged isotopic stacked record has been used in hundreds of paleoceanographic studies as a reference curve for developing age models and tying marine sedimentary records into a common stratigraphic framework.

Three years after the landmark paper by Imbrie et al. (1984), Martinson et al. developed an orbital timescale for the last 300 ka (Martinson et al., 1987) that they transferred

Figure 4 (a) The reference oxygen-isotope record established by the SPECMAP group (Spectral Mapping) by stacking five planktonic isotopic records. The age model was developed by phase-locking oxygen-isotope oscillations to orbital-forcing functions (Imbrie et al., 1984). (b) The detailed oxygen-isotope record from the last 300 ka obtained by stacking high-resolution benthic records (Pisias et al., 1984) and tied to orbital-forcing functions (Martinson et al., 1987). Isotopic stages are labeled according to the Pisias et al. (1984) modification of Emiliani's scheme.

Figure 5 In solid lines, variations in obliquity (upper panel) and precession (lower panel), and the corresponding frequency components extracted by band filtering the SPECMAP δ¹⁸O stack record (dashed line) over the past 780 ka. Reproduced from Imbrie J, Hays JD, Martinson DG, et al. (1984). The orbital theory of Pleistocene climate: Support from a revised chronology of the marine delta ¹⁸O record. In: Berger A et al. (eds.) *Milankovitch and Climate*, pp. 269–305. Dordrecht: Plenum Reidel.

to the stacked, benthic oxygen-isotope stratigraphy from Pisias et al. (1984; Figure 4(b)). Martinson et al. followed four different tuning strategies. This made it possible to test the robustness and accuracy of astronomical tuning for developing an Upper Pleistocene timescale. The error measured by the standard deviation about the mean of their four chronologies has an average magnitude of 2.5 ka. Transferring the final chronology to the stacked isotopic record of Pisias et al. (1984) leads to additional errors. The authors concluded this

final chronology has an average error of ±5 ka. Comparison of the younger portion of the Imbrie et al.'s chronology and Martinson et al.'s 300-ka chronology shows that ages of isotopic events agree to within the error bars (Figure 4).

The 300,000-year-long stacked δ¹⁸O record produced by Martinson et al. (1987) has been the preferred target record for upper Pleistocene benthic correlations since its publication. Having a higher temporal resolution, it also contains additional, short events of global significance that were not seen

in the SPECMAP planktonic $\delta^{18}\text{O}$ record. Beyond the last 300 000 ka, the longer, stacked benthic $\delta^{18}\text{O}$ record produced by Lisiecki and Raymo (2005) is now a widely used target for isotopic stratigraphy (see later).

Oxygen-Isotope Stratigraphy and the Imprint of the Primary Orbital Oscillations

The Deep Sea Drilling Project and the subsequent Ocean Drilling Program provided long, deep-sea sedimentary records that made it possible to look at climatic oscillations over the entire Pleistocene and beyond. These long records made it immediately obvious that the 100-ka oscillations only dominate the climate of the Earth over the last 600 ka, whereas the early Pleistocene variability is dominated by 41 ka, obliquity-related oscillations (i.e., Ruddiman et al., 1986). The exact timing and mechanisms of this shift between dominant periodicities of the climate system are still a matter of debate. Some studies have concluded that the transition from 41 to 100 ka dominant oscillations was gradual, taking place approximately in the interval 1.0–1.2 to 0.6 Ma (Berger et al., 1994; Imbrie et al., 1993; Ruddiman et al., 1989). However, other studies favored a rapid transition at about 0.8–0.9 Ma (Bassinot et al., 1997; Pisias and Moore, 1981; Shackleton and Opdyke, 1976). Statistical detection of the mid-Pleistocene transition in mean and variance of Pleistocene $\delta^{18}\text{O}$ records indicates that Earth's climate system may have experienced an abrupt change around 0.9 Ma (the so-called mid-Pleistocene revolution) that was characterized by an increase in ice mass and a global cooling (Maasch, 1988; Mudelsee and Stattegger, 1997).

The dominance of the 100-ka oscillation in the Upper Pleistocene is a major puzzle of the astronomical theory of climates since eccentricity variations of the Earth's orbit lead to only minor changes in the insolation budget (see review of this problem in Imbrie et al., 1993). Numerous authors have proposed that this 100-ka oscillation may result from non-linear response of the climate system that would transfer power from the envelope of the precession oscillations (i.e., Imbrie et al., 1993). Numerical modeling has suggested that the existence of large Northern Hemisphere ice sheets is an essential condition for developing the sawtooth 100-ka oscillations of the late Pleistocene (i.e., Imbrie et al., 1993; Le Treut and Ghil, 1983; Saltzman, 1987).

State of the Art and Limits of the Marine Oxygen-Isotope Stratigraphy

Improvement in the Marine Oxygen-Isotope Stratigraphy

Orbital tuning provides a global reference standard for dating long, continuous sediment records. However, the approach is not without its problems. Subsequent revisions of the 0–780 ka SPECMAP timescale showed, for instance, that several oscillations predicted by the astronomical theory of climate (in isotopic stages 17 and 18) were apparently missing in the stacked record (Bassinot et al., 1994; Shackleton et al., 1990). Their absence is related to (1) the incompleteness of some of the isotopic records that reached those stages and to (2) an erroneous Brunhes–Matuyama magnetic reversal age assignment in the age model developed at the first step of the

Imbrie et al. (1984) tuning approach. $^{40}\text{Ar}/^{39}\text{Ar}$ radiometric dating of the Brunhes–Matuyama magnetic boundary gives an age of about 780 ka (Baksi et al., 1992), significantly older than the K/Ar age (730 ka) available in the early 1980s, and used by Imbrie et al. (1984) to constrain their initial age model. Although the time constraint at the B/M boundary was removed midway in Imbrie et al.'s orbital-tuning approach, it is quite clear that the final age model suffered from this erroneous tie point.

Applying astronomical tuning strategies with a higher degree of freedom (i.e., no initial age assignment to the B/M boundary) on carefully selected, high-resolution isotopic records, Shackleton et al. (1990) and Bassinot et al. (1994) obtained astronomical ages for the Brunhes–Matuyama magnetic reversal that are in good agreement with $^{40}\text{Ar}/^{39}\text{Ar}$ radiometric ages (Figure 6). The Shackleton et al. (1990) record extends back to 2.5 Ma, and all the magnetic reversal age assignments are in good accordance with $^{40}\text{Ar}/^{39}\text{Ar}$ radiometric ages. These examples illustrate the fact that theoretical precision of astronomical timescales (usually a few thousand years) may actually mask potential, larger uncertainties related to the tuning strategy and/or to incompleteness of paleoclimatic records used to provide the stratigraphic framework on which the astronomical tuning is conducted. This implies that great care should be taken in selecting isotopic records used as references.

Developing a Global, Reference Curve

In order to build a globally meaningful stratigraphic reference curve, a time-consuming and robust approach is to use as many good and coherent oxygen-isotope records as possible; this is the approach followed by Lisiecki and Raymo (2005). These authors recently developed a 5.3 My stack (the 'LR04' stack) of benthic $\delta^{18}\text{O}$ records from 57 globally distributed sites aligned by an automated graphic correlation algorithm (Figure 7). They developed an age model for the Pliocene–Pleistocene, obtained from tuning the $\delta^{18}\text{O}$ stack to a simple ice model based on 21 June insolation at 65°N (Imbrie and Imbrie, 1980). Including all sources of errors (i.e., uncertainty in the orbital solution, number of records covering the oldest interval analyzed, assumed response time of the ice sheets), the authors estimated the uncertainty in the LR04 age model to be ± 6 ka from 3 to 1 Ma (Lower Pleistocene) and ± 4 ka from 1 to 0 Ma (Upper Pleistocene). The LR04 age model, designed to minimize changes in global sedimentation rates, generally supports the SPECMAP timescale back to 625 ka. As to date, the LR04 record is one of the most widely used reference for benthic oxygen isotopic stratigraphy of the Pliocene–Pleistocene.

Limits of Marine Oxygen-Isotope Stratigraphy

The accuracy of oxygen-isotope stratigraphy and its use in paleoceanographic studies rest on the basic assumption that global $\delta^{18}\text{O}$ variations recorded in the remains of marine organisms are mainly related to ice-volume changes and are, therefore, synchronous to within the mixing rate of the ocean (~ 1000 years). However, for detailed and accurate correlations at major climatic terminations, this set of assumption has its

Figure 6 Lower panel, the SPECMAP isotopic record (Imbrie et al., 1984). Upper panel, the low-latitude stack (Bassinot et al., 1994). The yellow and dark blue connections indicate the missing cycles from the SPECMAP stack that lead to a revision of the orbital solution in the astronomical timescale of the low-latitude stack. This new tuning solution led to a revised age of the Brunhes–Matuyama reversal (found at the base of isotopic stage 19), in good agreement with Ar/Ar dates.

Figure 7 The isotopic curve LR04 obtained by stacking 57 global benthic isotopic records. Age model was obtained through orbital tuning (Lisiecki and Raymo, 2005). To this date, this record is one of the most widely used for isotopic stratigraphy of the Plio–Pleistocene.

limits as shown recently by the radiocarbon dating of two high-resolution records, one from the Iberian margin (Atlantic) and the other from the eastern equatorial Pacific. This study revealed that the benthic $\delta^{18}\text{O}$ signal at the Pacific site lagged the Atlantic site by 3.9 ka across the last termination, a difference which is not explained by ocean mixing alone (Skinner and Shackleton, 2005). This lag has been chiefly attributed to the temperature-related part of the benthic Foraminifera $\delta^{18}\text{O}$ records, with the temperature increase in the deep Pacific being

significantly delayed relative to the ice-related $\delta^{18}\text{O}$ change of seawater across the last deglaciation.

Beyond the time interval that can be precisely radiochronologically dated, over the last six terminations, the analysis of sedimentation rates derived from the alignment of benthic $\delta^{18}\text{O}$ confirmed that there is a statistically significant Atlantic lead over the Pacific benthic $\delta^{18}\text{O}$ change that exceeds the delay expected from ocean mixing rates (Lisiecki and Raimo, 2009). To circumvent part of this problem and provide

paleoceanographers with more accurate stratigraphic targets across terminations, Lisiecki and Raimo (2009) produced two benthic stacked records, one for the Atlantic Ocean and the other for the Pacific Ocean. But diachronisms are not only restricted to interbasin correlations. Studies based on well-dated Atlantic, Indian, and Pacific sediments across the last termination suggest that, although some $\delta^{18}\text{O}$ deglacial changes are rapidly transferred to intermediate water depths, they can take an additional ~ 1500 years to reach the deep waters of the same basin (Labeyrie et al., 2005; Waelbroeck et al., 2006).

All the above results remind us that, while most of the $\delta^{18}\text{O}$ signal recorded in benthic carbonates is ice volume related and globally distributed to within the mixing rate of the ocean, complex circulation schemes and hydrological changes such as temperature modifications can lead to inter- and intra-basin diachronisms of up to a few thousand years across terminations. This should be taken into account for detailed stratigraphic correlations, and should be also carefully kept in mind when using benthic $\delta^{18}\text{O}$ records as a proxy for the timing of ice volume changes. This includes the studies that compare the phases of different proxies to $\delta^{18}\text{O}$ changes in a single sediment core.

Oxygen Isotope Composition of Seawater

E J Rohling, The Australian National University, Canberra, ACT, Australia

© 2013 Elsevier B.V. All rights reserved.

Introduction

This article deals with processes that affect the ratio of the two most common stable isotopes of oxygen in seawater and explores ways in which this has changed during the Quaternary. Both text and figures draw heavily on the water-based oxygen isotope part of a previously published essay on stable oxygen and carbon isotopes in Foraminifera (Rohling and Cooke, 1999). In contrast to the current text, which offers only the fundamental key references, the essay of Rohling and Cooke (1999) contains a very extensive set of references, and would therefore be a useful first step for further and more specialized reading.

Natural Abundance, Measurement, and Physicochemical Behavior

Oxygen exists in nature in the form of three stable isotopes: ^{16}O , ^{17}O , and ^{18}O . Their relative natural abundances are 99.76, 0.04, and 0.20%, respectively. Because of the higher abundances and the greater mass difference between ^{16}O and ^{18}O , research on oxygen isotope ratios normally concerns $^{18}\text{O}/^{16}\text{O}$ ratios.

The word isotope (Greek, meaning 'equal places') implies that the various isotopes occupy the same position in the Periodic Table. The difference between the atomic masses of the isotopic species for each element consists of a different number of neutrons in the nucleus, but isotopes have the same number of protons. The oxygen isotope $^{16}_8\text{O}$ contains 8 protons and 8 neutrons, giving it an atomic mass of 16. The isotope $^{18}_8\text{O}$ contains 8 protons and 10 neutrons, giving it an atomic mass of 18.

While the absolute abundances of minor isotopes (such as ^{18}O) cannot be determined accurately, it is still possible to get quantitative results by comparing the result given for a known external standard with that for the unknown sample. These differences in isotope ratios, known as δ values, are defined as:

$$\delta_{\text{sam}} = \frac{R_{\text{sam}} - R_{\text{std}}}{R_{\text{std}}} \times 1000$$

Here, sam is the sample value and std is the standard or reference value. These variations in composition are given in delta (δ) notation and are reported in parts per thousand (per mille, ‰). R stands for the heavy/light ratio between the abundances of any two isotopes (e.g., $^{18}\text{O}/^{16}\text{O}$). A positive δ value indicates enrichment in the heavy isotope, relative to the standard, and conversely, depletion is shown by a negative δ value. The standard used today in the analysis of $\delta^{18}\text{O}$ in water is the Vienna Standard Mean Ocean Water (VSMOW).

All isotopes of a given element contain the same number and arrangement of electrons, and so broadly display similarity in their chemical behavior. However, the mass differences of

different isotopes impose subtle differences in their physicochemical properties. The mass differences are particularly important in light elements (low numbers in the Periodic Table). Molecules vibrate with a fundamental frequency which depends on the mass of the isotopes from which they are composed. The resultant differences in dissociation energy of the light and heavy isotopes imply that bonds formed by light isotopes are weaker than those formed by heavy isotopes. Hence, as a rule of thumb, molecules comprised of the light isotopes react somewhat more easily than those comprised of the heavy isotopes.

The partitioning of isotopes between substances with different isotopic compositions is called 'fractionation.' The fractionation factor (α), which quantifies isotopic fractionation between two substances A and B, is defined as $\alpha = R_A/R_B$. Here, R_A and R_B are the heavy/light ratios between the abundances of any two isotopes (e.g., $^{18}\text{O}/^{16}\text{O}$) in the exchanging chemical compounds A and B, respectively. Fractionation mainly results from: (1) isotope exchange reactions and (2) kinetic effects. Isotope exchange reactions concern partitioning of isotopes between phases that are in equilibrium, and are therefore also known as 'equilibrium isotope fractionation' processes. Processes of equilibrium fractionation are essentially temperature dependent. Kinetic effects cause deviations from the simple equilibrium processes due to different rates of reaction for the various isotopic species (due directly to vibration differences, or indirectly through differences in bonding energies). Important kinetic effects are associated with diffusion.

Processes Controlling Oxygen Isotope Ratios in Seawater

The oxygen isotope ratio of seawater is intimately linked with fractionation processes within the hydrological cycle. Schematically, this cycle is comprised of evaporation, atmospheric vapor transport, precipitation, and subsequent return of freshwater to the ocean (directly via precipitation and via runoff or iceberg melting). Long-term storage of freshwater in aquifers and especially ice sheets is also important for seawater isotope ratios (Figure 1). Formation and melting of seasonal sea ice imposes strong local variability. Finally, the spatial distribution of oxygen isotopes in the world's oceans depends on processes of advection and mixing of water masses from different source regions with different isotopic signatures. The various influences are discussed below, but it should be noted that this forms only a basic introduction, and specialist texts and reviews should be consulted before advanced applications. Key texts and overviews can be found in Craig and Gordon (1965), Dansgaard (1964), Garlick (1974), Gonfiantini (1986), Hoefs (1997), Hoffmann and Heimann (1997), Joussame and Jouzel (1993), Jouzel et al. (1975), Majoube (1971), Merlivat

Figure 1 Schematic presentation of the hydrological cycle influences on oxygen isotope ratios. Effects on seawater are described in italics (reproduced from Rohling EJ and Cooke S (1999) Stable oxygen and carbon isotope ratios in foraminiferal carbonate. In: Sen Gupta BK (ed.) *Modern Foraminifera*, pp. 239–258. Dordrecht, The Netherlands: Kluwer Academic). The ‘fix’ comment refers to the storage of preferentially ^{16}O -enriched precipitation in ice sheets and groundwater, which constitutes a preferential removal of ^{16}O from the oceans and thus a relative ^{18}O -enrichment in the oceans.

and Jouzel (1979), Rohling and Cooke (1999), Rozanski et al. (1982, 1993), and Stewart (1975).

Evaporation

The isotopic exchange at the sea–air interface is given by:

Molecules composed of lighter isotopes have higher vapor pressures and the lighter molecular species are therefore preferentially enriched in the vapor phase. The fractionation factor for the equilibrium exchange is $\alpha_{l-v} = [^{18}\text{O}/^{16}\text{O}]_l / [^{18}\text{O}/^{16}\text{O}]_v$. The most commonly used relationship between α_{l-v} and temperature during evaporation is that given by Majoube (1971):

$$\alpha_{l-v} = \exp \{ (1.137 \text{ T}^{-2}) \times 10^3 - (0.4156 \text{ T}^{-1}) - 2.0667 \times 10^{-3} \}$$

where T is in Kelvin. This relationship illustrates a decrease in fractionation with increasing temperature. The fractionation causes a difference between $\delta^{18}\text{O}$ of seawater and $\delta^{18}\text{O}$ of vapor evaporated from that seawater equal to $\delta^{18}\text{O}_l - \delta^{18}\text{O}_v = 10^3 \ln(\alpha) \text{‰}$. At a temperature of 20 °C this difference amounts to about 9.8‰. The equilibrium enrichment factor ε is defined as $\varepsilon = \alpha - 1$, and is often reported as a ‰ value. For $\alpha = 1.010$, $\varepsilon = 10\text{‰}$.

Craig and Gordon (1965) found that, in addition to equilibrium fractionation, further fractionation should have occurred to explain their observations of stronger depletions in vapor than expected from equilibrium fractionation only. This further depletion is thought to be due to kinetic effects during molecular diffusion within the boundary layer between the water–air interface and the fully turbulent region (where no further fractionation occurs). Within that boundary layer, diffusion predominates because of slow atmospheric transport. The kinetic enrichment factor ($\Delta\varepsilon$) for oxygen isotopes depends on the relative air humidity (h) in the turbulent region outside the boundary layer, giving a relationship for most natural circumstances of $\Delta\varepsilon = 14.2 (1 - h) \text{‰}$, where h is presented as a fraction (i.e., 0.7 means 70% relative humidity).

Since diffusion rates depend on property gradients, the final isotopic composition of newly evaporated water also depends on the isotopic composition ($\delta^{18}\text{O}_{\text{atm}}$) of vapor already present in the turbulent region of the atmosphere, and on $\delta^{18}\text{O}$ of the surface water (Gonfiantini, 1986):

$$\delta^{18}\text{O}_E = \frac{1}{1 - h + \Delta\varepsilon} \left(\frac{\delta^{18}\text{O}_{\text{Sea surface}} - \varepsilon}{\alpha} - h\delta^{18}\text{O}_{\text{atm}} - \Delta\varepsilon \right)$$

Here, the $\delta^{18}\text{O}$, $\Delta\varepsilon$, and ε values, normally reported in ‰, are to be used in true form, that is, value $\times 10^{-3}$. It will be obvious that the preferential uptake of the lighter isotope during evaporation causes a shift to heavier $\delta^{18}\text{O}$ values in the remaining surface waters.

Precipitation and Atmospheric Vapor Transport

Fractionation processes during the formation of droplets are basically the same as during evaporation, but work in the opposite direction. Droplets are normally near equilibrium with atmospheric vapor, due to an absence of significant kinetic fractionation during condensation when relative humidity is 100%. The equilibrium fractionation factor for condensation is the same as that for evaporation and may therefore be determined with Majoube’s (1971) equation for the appropriate temperature, and then used in $\delta^{18}\text{O}_l - \delta^{18}\text{O}_v = 10^3 \ln(\alpha) \text{‰}$ to determine the isotopic composition of the droplets for any given atmospheric vapor composition.

Since condensation preferentially removes the heavier isotope ^{18}O , the $\delta^{18}\text{O}$ of the remaining atmospheric vapor becomes progressively more depleted. Relative to an original atmospheric vapor composition that is given by the composition of evaporated water ($\delta^{18}\text{O}_E$), the isotopic composition of the atmospheric vapor (AV) is approximated by $\delta^{18}\text{O}_{\text{AV}} = \delta^{18}\text{O}_E + 10^3(\alpha - 1) \ln f$ (Dansgaard, 1964), where α is the fractionation factor at condensation temperature and f is the fraction of atmospheric vapor remaining after rain-out (e.g., 0.7 if 70% of the evaporated water remains as atmospheric vapor due to 30% rain-out). The isotopic composition

of precipitation formed in equilibrium with the atmospheric vapor is found according to $\delta^{18}\text{O}_\text{P} - \delta^{18}\text{O}_\text{AV} = 10^3 \ln \alpha$. From these relationships, which represent a basic Rayleigh distillation process, it is immediately obvious that the first precipitation will be of a similar isotopic composition as the original seawater, and that a longer pathway from the source region (and consequently more rain-out) causes atmospheric vapor to become more and more depleted. New precipitation from this vapor reflects this depletion (Figure 2). As a result, precipitation is significantly more depleted at high latitudes than in the tropics (reaching values as low as -57‰ in Antarctica).

The magnitude of rain-out is strongly temperature dependent. As atmospheric vapor is transported toward colder regions, it experiences successive condensations. This effect – rather than temperature dependence of the fractionation factor – determines a basic quasilinear relationship of $0.69\text{‰}^\circ\text{C}^{-1}$ between $\delta^{18}\text{O}$ of precipitation and temperature, as has been observed for temperatures between -40 and $+15^\circ\text{C}$. Above 15°C , this relationship with temperature breaks down. There, mainly in areas with strong convection in the atmosphere, the so-called amount effect dominates. This effect approximately determines 1.5‰ depletion in the $\delta^{18}\text{O}$ of precipitation for every 100 mm increase in rainfall.

The changes in oxygen-isotope composition of atmospheric vapor and precipitation affect surface waters in the world's oceans through addition of freshwater via precipitation directly onto the sea surface or via runoff. Arid, evaporative areas demonstrate the evaporative surface water $\delta^{18}\text{O}$ enrichment. Regions in reasonable proximity to a river mouth will be affected by the volumetrically weighted average isotopic composition of precipitation over the river's catchment area. A

high-latitude river system imports freshwater with generally lower $\delta^{18}\text{O}$ values than those of a low latitude river – for example, the average (pre-Aswan dam) Nile river $\delta^{18}\text{O}$ composition was near -2‰ , whereas the Arctic McKenzie river discharges waters with a composition around -20‰ .

Two crucial 'delayed' responses need to be taken into account. Both result from long-term storage of precipitation. Besides runoff from rivers, icebergs calving from continental ice sheets also provide a source of 'continental' freshwater. Icebergs import into the ocean a 'fossil' isotopic signature depending on the age of the calving ice. Since ice cores in the Greenland and Antarctic Ice Sheets penetrate ice aged well over 100 000 years, and (in Antarctica) even reach 900 000 years, the isotopic signatures of bergs shed by those ice sheets should not be considered as a result of the present-day freshwater cycle. Similarly, but much less importantly, fossil waters may accumulate in aquifers and at a much later stage contribute to river discharge into the oceans, thus causing deviations from the isotopic compositions of rivers expected from precipitation in the catchment basin. Fossil ground waters may be as old as 35 000 years.

Long-Term 'Storage': Glacial Ice Volume

Apart from delayed return of 'fossil' isotopic signals back into the ocean, long-term storage systems, such as glacial ice sheets and – to a much lesser extent – major aquifers, may also affect the global $\delta^{18}\text{O}$ balance. Because the timescales of storage (on the order of 10^4 – 10^5 years) exceed those of ocean ventilation (on the order of 10^3 years), the modification of ocean water $\delta^{18}\text{O}$ due to these storage effects will be mixed throughout the ocean and, therefore, will be manifest both at the surface and at depth.

The main influence is related to the volume of glacial ice sheets. These are built up by high latitude precipitation (snow) at very low temperatures toward the end of the Rayleigh distillation process (Figure 1), and so record extremely light $\delta^{18}\text{O}$ values (Figure 2). This preferential sequestration of ^{16}O in ice sheets leaves the oceans relatively enriched in ^{18}O . At the same time, build-up of ice volume lowers global sea level. Research on $\delta^{18}\text{O}$ changes in fossil carbonate, complemented by accurate constraints on sea level changes from fossil coral reef studies, suggests that the relationship between sea level lowering and mean oceanic $\delta^{18}\text{O}$ enrichment approximates $0.012 \pm 0.001\text{‰m}^{-1}$. Work on $\delta^{18}\text{O}$ values of actual glacial waters, trapped as pore water in marine sediments, has revised this relationship to about $0.010 \pm 0.001\text{‰m}^{-1}$ (see the Section 'Processes Controlling Oxygen Isotope Ratios in Seawater').

The above relationships provide a sound working model for a time with a well-matured ice sheet, but it should be noted that the processes behind it may invoke a more nonlinear relationship for growing or recently matured ice sheets. Ice sheets go through a cycle of growth (young), equilibrium (mature), and decay. Mature ice sheets are mass balanced: ice accumulates at the surface, then flows from the surface to the bottom and out to the edges, where it is shed through iceberg calving and/or melting. Precipitation reaching the summit of a recently 'matured' ice sheet may therefore be significantly more depleted in $\delta^{18}\text{O}$ than that lost from the edges at the same time,

Figure 2 The relationships between isotopic composition of atmospheric vapor and precipitation relative to evaporation with an original composition of -10‰ and fractionation at a constant temperature of 15°C . Reproduced from Rohling EJ and Cooke S (1999) Stable oxygen and carbon isotope ratios in foraminiferal carbonate. In: Sen Gupta BK (ed.) *Modern Foraminifera*, pp. 239–258. Dordrecht, The Netherlands: Kluwer Academic.

which concerns ice deposited when the ice sheet was much 'younger' (smaller/lower with higher temperatures than over the mature ice sheet). Therefore, an ice sheet may be mass balanced, but not yet isotopically balanced. After a significant lag ($>10^4$ years), the ice reaching the edges will be that built up on a mature ice sheet, and the isotopic composition of accumulating and calving ice will be more or less the same; only then will the ice sheet have reached isotopic balance.

Sea Ice Freezing and Melting

The $\delta^{18}\text{O}$ of newly formed sea ice is $2.57 \pm 0.10\text{‰}$ enriched relative to that of seawater. Although this is a small offset compared with the massive salinity difference between seawater (S usually >30 p.s.u.) and sea ice ($S < 20$ p.s.u.), the isotopic difference still imposes a major seasonal fluctuation associated with sea ice formation and melting. It is tempting to assume that such seasonal influences would cancel out in the long term, but increases in surface water salinity due to salt (brine) rejection when sea ice is formed may lead to convection and transport of existing surface waters into the ocean interior. The removed surface waters would be replaced by surface waters that were not (as much) affected by freezing processes, and when the sea ice subsequently melts the isotopic effect would not cancel out. The 'brine rejection' influence of sea ice formation can thus lead to significant regional vertical and horizontal $\delta^{18}\text{O}$ anomalies.

Advection and Diffusion

Advection and mixing of water masses from different source areas strongly affect the basic $\delta^{18}\text{O}$ composition observed at any site. Each 'source area' concerns a basin or region – which may be very remote from the study site – where surface waters are 'imprinted' with a certain $\delta^{18}\text{O}$ composition, through action of the freshwater cycle, freezing/melting of sea ice, etc. This 'preset' isotopic composition may be considered as a virtually conservative property for the newly formed water

mass, as long as this water mass does not come into contact with other sinks or sources of $\delta^{18}\text{O}$, notably the freshwater cycle. In practice, therefore, $\delta^{18}\text{O}$ may be used as a conservative tracer for transport (advection) and mixing of water masses in the subsurface ocean.

A mixing end product receives a $\delta^{18}\text{O}$ composition resulting from the volumetrically weighted averaged $\delta^{18}\text{O}$ compositions of its components: $\delta^{18}\text{O}_{\text{end product}} = (A \delta^{18}\text{O}_A + B \delta^{18}\text{O}_B + C \delta^{18}\text{O}_C) / (A + B + C)$ where A , B , and C are the volumes of three mixing components and $\delta^{18}\text{O}_A$, $\delta^{18}\text{O}_B$, and $\delta^{18}\text{O}_C$ are their isotopic compositions, respectively. Any change in relative proportions or the individual 'preset' isotopic compositions of the various mixing components would, therefore, affect the isotopic composition of the mixing end product. Any change in isotopic composition must therefore be viewed within the broader context of water mass formation and mixing on ocean-wide scales, and should not be purely ascribed to local changes in surface forcing (e.g., freshwater budget). It has been found that these hitherto 'ignored' processes may be particularly important for the global $\delta^{18}\text{O}$ distribution during times with comprehensively rearranged ocean circulation (e.g., glacial periods).

Global Seawater $\delta^{18}\text{O}$ Distribution

The combined processes listed above result in a global seawater $\delta^{18}\text{O}$ distribution. A current collection exists of over 20000 seawater $\delta^{18}\text{O}$ measurements made since about 1950 (Schmidt et al., 1999). The date of that reference refers to the original appearance date, based on compilations made for two publications (Bigg and Rohling, 2000; Schmidt et al., 1999), but the database is current up to the present. From that database, Figure 3 shows the integrated surface ocean (top 50 m) $\delta^{18}\text{O}$ field interpolated onto a $4^\circ \times 5^\circ$ grid. Data are registered from all depths and are accompanied by a variety of other oceanographic measurements, most notably salinity. A diverse series of search modes allows extraction of data from the database according to specific research needs.

Figure 3 Example of output from the Schmidt et al. (1999) global sea water $\delta^{18}\text{O}$ database (extracted 13 January 2012). The image shows surface water $\delta^{18}\text{O}$ integrated over the top 50 m on a $4^\circ \times 5^\circ$ grid.

Oxygen Isotope Ratios in Seawaters of the Quaternary

Oxygen isotope ratios in seawater have changed considerably in the geological past. Apart from regional and short-term temporal variability, there have been fluctuations on global scales and of long ($\geq 10^4$ years) duration. These global-scale and long-duration fluctuations were mostly associated with changes in continental ice volume. In this section, it is discussed how we know of such past $\delta^{18}\text{O}$ variations.

Seawater $\delta^{18}\text{O}$ Inferred from Measurements on Fossil Carbonates

By far the most common manner to evaluate past changes in seawater $\delta^{18}\text{O}$ is via an indirect method, which starts with the analysis of $\delta^{18}\text{O}$ in fossil carbonates – mostly the shells of unicellular zooplankton (Foraminifera). The stable isotopes of oxygen (and carbon) in carbonates are analyzed by mass spectrometric determination of the mass ratios of carbon dioxide (CO_2) obtained from the sample, with reference to a standard carbon dioxide of known composition. The CO_2 is produced by reaction of the carbonate with phosphoric acid: $\text{CaCO}_3 + \text{H}_3\text{PO}_4 \rightleftharpoons \text{CaHPO}_4 + \text{CO}_2 + \text{H}_2\text{O}$. The $\delta^{18}\text{O}$ of carbonates is not measured against the VSMOW standard but against the Vienna Pee Dee Belemnite (VPDB) standard. The VPDB and VSMOW scales relate to one another according to $\delta^{18}\text{O}_{\text{VSMOW}} = 1.03092 \delta^{18}\text{O}_{\text{VPDB}} + 30.92$.

There are several processes that determine the oxygen isotope composition of newly formed foraminiferal carbonate. Firstly, equilibrium fractionations between water and the various carbonate species (CaCO_3 , H_2CO_3 , HCO_3^- , CO_3^{2-}) determine an important temperature influence on the $\delta^{18}\text{O}$ of foraminiferal carbonate. Secondly, there are considerable kinetic effects, notably as the shell growth-rate changes through the organism's life cycle. To minimize the influence of kinetic effects, often grouped under the name 'vital effects,' analytical strategies have been designed that focus on time series of single species (to avoid vital effect differences between species), and that use very narrow size windows from which specimens are picked for analysis (to minimize changes in the vital effects with growth). There are other, currently less well-constrained influences, such as the concentration of the carbonate ion (CO_3^{2-}). Stable isotope ratios in carbonate are discussed in a separate chapter, and the present discussion is restricted to equilibrium fractionation between water and carbonate, which holds important clues regarding the way we can determine past seawater $\delta^{18}\text{O}$ changes.

The overall reaction involved in the precipitation of carbonate is: $\text{Ca}^{2+} + 2\text{HCO}_3^- \rightleftharpoons \text{CaCO}_3 + \text{CO}_2 + \text{H}_2\text{O}$. Where oxygen is concerned, the various carbonate species in seawater, including the predominant bicarbonate (HCO_3^-) ion, are isotopically equilibrated with the water (H_2O) molecules. The overall equilibrium fractionation between calcite and water is a function of temperature. For the range of 0–500 °C, O'Neil et al. (1969) determined that the equilibrium fractionation factor α_{c-w} between calcite and water (α_{c-w}) changes with temperature according to: $\alpha_{c-w} = \exp\{(2.78 T^{-2}) \times 10^3 - 3.39 \times 10^{-3}\}$ where T is in Kelvin. Other workers have reported slightly different equations, for example, with the last coefficient at

2.89×10^{-3} rather than 3.39×10^{-3} . The summary effect of equilibrium fractionation is a roughly 0.2‰ depletion in carbonate $\delta^{18}\text{O}$ for every 1 °C temperature increase, although Kim and O'Neil (1997) presented a more detailed relationship where the $\delta^{18}\text{O}$ change with temperature is more pronounced at low temperatures (up to $0.25\text{‰} \text{ } ^\circ\text{C}^{-1}$) than at higher temperatures (around $0.2\text{‰} \text{ } ^\circ\text{C}^{-1}$).

A first observation to be made regarding planktonic Foraminifera is that several species may inhabit different depths at different stages of their life cycle. Since temperature decreases with increasing depth in the surface oceans, vertical migrations influence equilibrium fractionation. This again is a problem that can be circumvented by analytical strategy; time series of data are considered for single species in very narrow size windows, so the habitat-depth effect should be similar for all and thus will not affect the inferred variability sea water $\delta^{18}\text{O}$ over time.

Simplified, therefore, a time series of $\delta^{18}\text{O}$ analyzed from fossil planktonic Foraminifera in a sediment core is dominated by two main variables: temperature variability and seawater $\delta^{18}\text{O}$ variability. The temperature changes can be 'corrected for' using other methods for estimating past seawater temperatures (e.g., Mg/Ca ratios in the foraminiferal carbonate, organic geochemical biomarker ratios, or statistical transforms of microfossil abundance variations). This then allows the estimation of past changes in seawater $\delta^{18}\text{O}$.

Time series of foraminiferal $\delta^{18}\text{O}$ and – by implication – seawater $\delta^{18}\text{O}$ illustrate that glacial ice volume has varied strongly over the last 2 million years, a period known on the geological timescale to fall within the Quaternary. During the last 400 000 years, the main variability can be seen as a rough sawtooth pattern with a 100 000-year rhythm of glacial–interglacial cycles, which is mainly related to global ice volume fluctuations (Figure 4). Ice sheets grew spasmodically over periods of roughly 90 000 years, reaching a maximum extent that was followed by a very abrupt ice volume reduction heralding the onset of an interglacial maximum with a typical mean duration of some 10 000 years. Between 0.4 and 1 million years ago, there was a less well-defined state, with a complex interplay between main periods of 100 000 and 41 000 years for the glacial cycles. Prior to 1 million years ago (especially in the interval between 2.5 and 1 million years ago), the glacial cycles followed a well-developed 41 000-year period, and in that period the glacial cycles did not have a conspicuously sawtoothed temporal structure (Figure 4). Following calibration with dated fossil coral reefs, the past $\delta^{18}\text{O}$ fluctuations were found to indicate that global ice volume has waxed and waned so much that global sea level variations occurred between 140 m below and 5–10 m above the present-day level. For the last glacial cycle, such studies suggested a relationship between sea level lowering and mean oceanic $\delta^{18}\text{O}$ enrichment in the region of $0.012 \pm 0.001\text{‰} \text{ m}^{-1}$.

Other Uses of Foraminifer-Based $\delta^{18}\text{O}$ in Paleoceanography

There have been recent forays into alternative uses of foraminiferal carbonate-based $\delta^{18}\text{O}$ that avoid the complications involved in deconvolving the carbonate $\delta^{18}\text{O}$ data in terms of past temperature and seawater $\delta^{18}\text{O}$. These studies have focused instead on the fact that, in specific settings, carbonate

Figure 4 A stacked record of stable oxygen isotope variations for the last 5.3 million years, constructed from 57 globally distributed deep-sea (benthic foraminiferal) records. Numbers indicate glacial (down = heavy $\delta^{18}\text{O}$ values) and interglacial (up = light $\delta^{18}\text{O}$ values) intervals. The dark/light bar at the bottom of each panel indicates (named) intervals of normal (dark) and reversed (light) geomagnetic polarity. Time is indicated in units of 1000 years (ka). Reproduced from Lisiecki LE and Rayme ME (2005) A Pliocene-Pleistocene stack of 57 globally distributed benthic $\delta^{18}\text{O}$ records. *Paleoceanography* 20: PA1003, <http://dx.doi.org/10.1029/2004PA001071>.

$\delta^{18}\text{O}$ offers a very useful approximation of past seawater density, because it is a function of temperature and the hydrological budget (as is density). Thus the carbonate $\delta^{18}\text{O}$ data can be used as a dynamic proxy for the reconstruction of density gradients with depth or in a spatial sense. Lynch-Stieglitz et al. (1999) used depth transects of benthic foraminiferal $\delta^{18}\text{O}$ data on both sides of Florida Straits in geostrophic (where the horizontal pressure gradient is balanced by the Coriolis force) current intensity reconstructions of the Florida Current during glacial times. Billups and Schrag (2000) argued that, in tropical and subtropical regions, the $\delta^{18}\text{O}$ data obtained from various planktonic foraminiferal species may be used to reconstruct past changes in spatial surface-water density gradients, on a global scale.

Another line of work has focused on the sea-level-dependent concentration effect on $\delta^{18}\text{O}$ in evaporative marginal seas with limited connection to the open ocean. A key study along these lines concerns the Red Sea, a highly evaporative basin with a very

shallow (137 m) connection to the open ocean. As sea level varied on glacial-interglacial timescales between about 130 m below the present and about 5 m above the present, the broadly triangular strait profile imposed very serious limitations on the amount of water exchange between the Red Sea and the open ocean. With lowering sea level, the exchange is progressively inhibited, which increases the residence time of waters inside the highly evaporative Red Sea. As a consequence of this sea level effect, the glacial-interglacial $\delta^{18}\text{O}$ contrast in the Red Sea is amplified about five times relative to the open ocean. By quantifying the relationship between sea level and Red Sea $\delta^{18}\text{O}$ change, Siddall et al. (2003) developed a new technique for reconstruction of global sea level variability, using foraminiferal $\delta^{18}\text{O}$ records from central Red Sea sediment cores. Records employing this method have been further developed in detail through the last 520,000 years (Rohling et al., 2009, 2010; Figure 5). This technique relies on a physically defined

Figure 5 Sea level reconstruction from the Red Sea method (Rohling et al., 2009). Gray dots are individual values; blue line is a smoothing function so that individual data are spread around it a normal distribution with $1\sigma = 6$ m, which is the method's realistic uncertainty (Siddall et al., 2003). Green symbols denote benchmark data from U–Th dated corals and submerged speleothems. Panel (a) shows the record on its initial chronology, based on graphical correlation with the Antarctic EPICA Dome C temperature anomaly record (Jouzel et al., 2007). Panel (b) shows the record after a systematic adjustment of -4 ka, based on the offset seen in (a) between the Red Sea sea level record and the radiometrically dated points during the last deglaciation (19–8 ka) (Rohling et al., 2010). This brought midpoint ages for interglacials in the Red Sea record within 1.5% of the midpoint ages from radiometric datings (Rohling et al., 2010). Although a good match was obtained on glacial–interglacial timescales, further improvements to the chronology remain needed on shorter timescales. Data available from the DATA link with Rohling et al. (2010) at <http://www.highstand.org/erohling/ejrhome.htm>.

relationship between Red Sea $\delta^{18}\text{O}$ and sea level in the strait and is therefore fundamentally different in approach and sensitivity to the global deep-sea $\delta^{18}\text{O}$ records shown in Figure 4.

'Direct' Measurement of Past Seawater

Recent work has introduced significant new insight into the history of seawater $\delta^{18}\text{O}$. Adkins et al. (2002) measured $\delta^{18}\text{O}$ profiles for pore waters extracted from marine sediment cores. The pore water profile reflects the past bottom water $\delta^{18}\text{O}$ conditions, subject to advective and diffusive processes within the sediment, and the Last Glacial Maximum ($\sim 20,000$ years ago) stands out as the interval with highest $\delta^{18}\text{O}$ values (i.e., maximum ice volume). Hence the actual Last Glacial Maximum bottom water $\delta^{18}\text{O}$ was determined from sediment cores for a variety of sites around the world, from a range of different water depths. The sea level difference between the Last Glacial Maximum and the present was taken from other analyses, and overall, this study suggests that the actual relationship between sea level lowering and mean oceanic $\delta^{18}\text{O}$ enrichment is closer to $0.010 \pm 0.001\text{‰ m}^{-1}$. This indicates that the steeper relationship previously derived from carbonate-based $\delta^{18}\text{O}$ changes likely contained some residual temperature effects (i.e., glacial deep-water temperatures were colder than was assumed).

Introduction

What are Radioisotopes?

Atoms consist of a cloud of negatively charged electrons circling around a positively charged nucleus. The nucleus accounts for most of the atomic mass and is composed of positively charged protons and uncharged neutrons. Electrons and protons have electrical charges of equal magnitude but are opposite in polarity. They occur in equal numbers, so that single atoms have no net charges. The number of protons is referred to as the atomic number (Z). Each element of the periodic table is characterized by its atomic number (i.e., its number of protons), which dictates the number of electrons and the configuration of valence electrons establishing the chemical properties of the atom.

Unlike the number of protons and electrons, the number of neutrons in the nucleus (N) can vary without changing the chemical properties of the atom. This is because changing the number of uncharged neutrons in the nucleus does not require changing the number of electrons and the configuration of the valence electrons. A given element can thus consist of atoms with different numbers of neutrons. These atoms have similar chemical properties, but different atomic masses or mass number ($A = Z + N = \text{number of protons} + \text{number of neutrons}$). Atoms of the same element (i.e., with identical Z) but with different masses (i.e., with different A) are called isotopes. By convention, isotopes are identified by the chemical symbol of the element and the atomic mass number (A) in superscript (e.g., ^{238}U , ^{235}U).

Depending on the relative proportion of protons and neutrons, the nucleus of an atom can be stable (resulting in a stable isotope) or unstable (resulting in a radioisotope). Radioisotopes 'decay' spontaneously by changing the proton/neutron ratios of their nucleus until they reach a stable nuclear configuration. They do so by emitting energetic particles (alpha or beta) from their nuclei. During alpha decay, the nucleus emits an alpha particle consisting of two neutrons and two protons. Consequently, the daughter (i.e., the product of the decay) has lost four atomic mass units ($A_{\text{daughter}} = A_{\text{parent}} - 4$) and two protons ($Z_{\text{daughter}} = Z_{\text{parent}} - 2$). The atom that undergoes decay thus becomes a different element with different chemical properties (e.g., $^{238}\text{Th} \rightarrow ^{234}\text{Ra} + \alpha$). During beta decay, the nucleus ejects an electron, which can be charged negatively (negatron) or positively (positron). When the nucleus emits a negatron, one of the neutrons in the nucleus becomes a proton. Consequently, the daughter keeps the same atomic mass as the parent atom ($A_{\text{daughter}} = A_{\text{parent}}$) but gains one proton ($Z_{\text{daughter}} = Z_{\text{parent}} + 1$), thereby also changing its chemical identity (e.g., $^{234}\text{Th} \rightarrow ^{234}\text{Pa} + \beta^-$). When the nucleus emits a positron, one of the protons in the nucleus becomes a neutron.

General Applications of Radioisotopes

The rate at which radioisotopes decay ($-dN/dt$; i.e., the rate at which atoms of the parent are transformed into daughters) is proportional to the number of atoms of the radioisotope present (N):

$$-dN/dt = \lambda N \quad [1]$$

where λ is the decay constant, which is a fixed property for a particular radioisotope and is independent of environmental factors (temperature, pressure, etc.). λN is also called the 'activity' of the radioisotope N and is often expressed in 'disintegration per minutes' (dpm).

Integrating this equation results in a simple exponential law that describes the change in the number of parent isotopes as a function of time:

$$N(t) = N_{(0)} e^{-\lambda t} \quad [2]$$

where $N(t)$ is the number of parent isotopes remaining at time t and $N_{(0)}$ is the initial number of parent isotopes at $t=0$.

If we know $N_{(0)}$, measuring $N(t)$ provides a means to calculating the period of time over which decay occurred ($t = -1/\lambda \ln(N(t)/N_{(0)})$). Estimating $N_{(0)}$ is often the tricky part of this approach. Nonetheless, applying this simple equation provides 'clocks' that have been widely used to date environmental samples on timescales ranging from billions of years to a few months (see the section on chronology).

Besides their wide applications in chronology, radioisotopes also provide quantitative information on a wide range of environmental processes. This is particularly true for the radioactive isotopes produced in the three naturally occurring radioactive decay series (Table 1). These decay series are initiated by the very slow radioactive disintegration of three long-lived isotopes: ^{238}U (half-life = 4.47×10^9 years), ^{235}U (half-life = 7.04×10^8 years), and ^{232}Th (half-life = 1.41×10^{10} years). The half-life is the amount of time it takes for half of the radioactive atoms in a sample to decay. The atoms of ^{238}U , ^{235}U , and ^{232}Th that now decay were produced by nucleosynthesis in supernovas billions of years ago, but because of their very long half-lives, they still persist to this day. When left undisturbed, all the daughters in the series have the same decay rate (or the same 'activity'). The decay series is then said to be in 'secular equilibrium.' In this situation, each radioactive isotope of the series decays at a rate that is equal to the rate at which it is produced (which is the rate at which its parent is decaying). Ultimately, the rate of decay of all the daughters is dictated by the rate of decay of the initial parent (^{238}U , ^{235}U , or ^{232}Th), which very slowly decreases with time.

Table 1 Natural decay series initiated by the ^{238}U , ^{235}U , and ^{232}Th

	U-238 series						Th-232 series						U-235 series					
Np																		
U	U-238 4.47 × 10 ⁹ yr		U-234 2.48 × 10 ⁵ yr										U-235 7.04 × 10 ⁸ yr					
Pa	↓	Po-234 1.18 m	↓										↓	Po-231 3.2 × 10 ⁴ yr				
Th	Th-234 24.1 d		Th-230 7.52 × 10 ⁴ yr				Th-232 1.41 × 10 ¹⁰ yr		Th-228 1.90 yr				Th-231 25.6 h			Th-227 18.6 d		
Ac			↓				↓	Ac-228 6.13 h	↓					↓	Ac-227 22.0 yr			
Ra			↓				↓	↓	↓							↓		
Fr																		
Rn			Rn-222 3.825 d															
At			↓															
Po			Po-218 3.05 m		Po-214 1.6 × 10 ⁻⁷ s		Po-210 138.4 d		Po-216 0.158 s	65%	Po-212 30 × 10 ⁻⁷ s					Po-215 1.63 × 10 ⁻³ s		
Bi			↓	Bi-214 19.7 m	↓	Bi-210 5.0 d	↓		↓	Bi-212 60.5 m	↓					↓	Bi-211 2.16 m	
Pb			Pb-214 26.8 m		Pb-210 223 yr		Pb-206		Pb-212 10.6 h	35%	Pb-208					Pb-211 36.1 m		Pb-207
Tl											Tl-208 3.1 m						Tl-207 4.79 m	

The usefulness of these isotopes in environmental sciences stems from the fact that processes on the surface of the Earth often separate daughters from parents, thereby perturbing secular equilibrium (Boudron et al., 2003). This arises because the successive daughters of the decay series consist of different elements with very different chemical properties (Table 1). For instance, while uranium and radium are relatively soluble in water, thorium, protactinium, polonium, and lead have very low solubility and are readily removed from aqueous solutions by adsorption on surfaces of particles or sediments. On the other hand, radon is a gas and tends to diffuse into the atmosphere from the rocks or water where it is produced from the decay of radium. When an environmental process separates a daughter from its parent (for instance, when settling particles remove Th isotopes from seawater into the underlying sediment, thereby separating them from their more soluble parent uranium isotopes), the activity of daughter isotopes (i.e., the rate at which they decay) decreases and becomes lower than the activity of parent isotopes. Assuming steady state, we can write a simple mass balance equation stating that the rate at which the daughter is produced (i.e., the rate at which the parent decays or the activity of the parent; $\lambda_{\text{parent}}N_{\text{parent}}$) must be equal to the rate at which the daughter decays (i.e., the activity of the daughter; $\lambda_{\text{daughter}}N_{\text{daughter}}$) plus the rate at

which the daughter is removed by the environmental process (R_{daughter}). Thus

$$R_{\text{daughter}} (\text{atoms min}^{-1}) = \lambda_{\text{parent}}N_{\text{parent}} - \lambda_{\text{daughter}}N_{\text{daughter}} \quad [3]$$

Measuring the difference in activity between parents and daughters in environmental samples (such as seawater, sediments, corals) thus provides means of quantifying the rate of removal of the daughter from the sample. In turn, determining the rate of removal of the daughter by a given process under different environmental conditions provides quantitative information on the relative intensity of this process under these environmental conditions and adds insight into the mechanisms involved. For instance, the parent isotope ^{238}U dissolved in seawater decays to its daughter ^{234}Th . Because uranium is very soluble, ^{238}U remains in seawater on average for 400 ka before being removed (mainly by incorporation into biogenic carbonates and basaltic rocks at mid-ocean ridges or by diffusion into anoxic sediments). ^{234}Th , on the other hand, being very insoluble, is quickly removed from seawater by adsorption on the surface of settling particles (a process called 'scavenging'). As a result, we find a deficit in the activity of ^{234}Th in seawater ($\lambda_{\text{Th-234}}N_{\text{Th-234}}$) compared to the activity of ^{238}U ($\lambda_{\text{U-238}}N_{\text{U-238}}$). Such a deficit is only found in the upper

water column because it is where particle concentrations and fluxes are sufficiently high to compete with the rapid rate of decay of ^{234}Th , whose half-life is only 24.1 days (Cochran and Masqué, 2003). In deeper water, particle concentrations and fluxes quickly decrease as a result of their remineralization, and the scavenging intensity resulting from this smaller particle flux is too small to remove ^{234}Th at a rate that would be comparable to its rapid rate of decay. Consequently, secular equilibrium between ^{238}U and ^{234}Th is essentially maintained below surface waters ($\lambda_{\text{U-238}}N_{\text{U-238}} = \lambda_{\text{Th-234}}N_{\text{Th-234}}$). As per eqn [3], the deficit in the upper water column is a quantitative estimate of the removal of ^{234}Th by scavenging from surface waters, and we find that it is larger in regions where biological productivity is higher. This observation clearly points to the export of biogenic particles from surface waters as the main variable regulating the scavenging of ^{234}Th and other insoluble elements from seawater. By measuring the ratio of the concentration of any constituent of the settling particles ($[X]$) to the activity of ^{234}Th in the settling material ($A_{\text{Th-234}}$), we can also calculate the export flux of this constituent (F_x):

$$F_x(\text{g min}^{-1}) = R_{\text{Th-234}}(\text{atoms min}^{-1}) \times [X]/A_{\text{Th-234}}(\text{g atoms}^{-1}) \quad [4]$$

This method has been widely used to estimate the export flux of carbon from surface to deep ocean water and evaluate the role of the marine biota in controlling the concentration of carbon dioxide in the atmosphere (Cochran and Masqué, 2003).

Applications of Radioisotope Tracers in Quaternary Paleooceanography

For Quaternary paleoceanographic applications, we are restricted to isotopes that are incorporated into paleoceanographic archives (mainly sediments, corals, or ferromanganese crusts) and that have half-lives long enough to persist on Quaternary timescales. The decay series initiated by ^{232}Th does not provide useful paleoceanographic tracers since the longest-lived radioisotope it generates (^{228}Ra) has a half-life of 5.75 years (Table 1). On the other hand, the ^{238}U and ^{235}U decay series both have one long-lived isotope with important paleoceanographic applications other than chronology (Francois, 2007; Henderson and Anderson, 2003). They are ^{230}Th (half-life = 75.38 ka) from the ^{238}U decay series and ^{231}Pa (half-life = 32.76 ka) from the ^{235}U decay series (Table 1). Information recorded in the sediment by these radioisotopes remains for a period of time equivalent to four or five times their half-life, beyond which their activity in sediment decreases to values that cannot be measured accurately. Paleooceanographic applications of these isotopes are thus largely limited to the last glacial cycle (i.e., the past 150 ka).

Paleoceanographic Applications Based on the Activity of ^{230}Th in Marine Sediments

^{230}Th is produced in seawater from the radioactive decay of ^{234}U (Figure 1). Since uranium resides in the ocean for

Figure 1 ^{234}U is leached from continental rocks by chemical weathering and added to the ocean by rivers and groundwater. ^{234}U decays in the ocean to produce ^{230}Th which is quickly adsorbed on settling particles and removed into marine sediments, a process called 'particle scavenging.'

about 400 ka, it is well mixed and its seawater concentration or activity is uniform ($^{sw}A_{\text{U-234}} = 2910 \text{ dpm m}^{-3}$), resulting in a constant rate of formation of ^{230}Th in seawater (rate of formation of ^{230}Th ($\text{atoms m}^{-3} \text{ min}^{-1}$) = ^{234}U decay rate = $2910 \text{ atoms m}^{-3} \text{ min}^{-1}$). The rate of production of ^{230}Th in seawater ($\beta_{\text{Th-230}}$) is often expressed in $\text{dpm m}^{-3} \text{ year}^{-1}$:

$$\beta_{\text{Th-230}} = \lambda_{230} \times \text{Rate of formation of } ^{230}\text{Th} (\text{atoms m}^{-3} \text{ min}^{-1}) \quad [5]$$

$$\beta_{\text{Th-230}} = \lambda_{230} \times ^{sw}A_{\text{U-234}} \quad [6]$$

$$\beta_{\text{Th-230}} = 9.16 \times 10^{-6} \text{ year}^{-1} \times 2910 \text{ dpm m}^{-3} \quad [7]$$

$$\beta_{\text{Th-230}} = 0.0267 \text{ dpm m}^{-3} \text{ year}^{-1} \quad [8]$$

As indicated above, Th is highly insoluble in seawater, and ^{230}Th produced from the decay of dissolved ^{234}U is promptly removed from the water column by scavenging (i.e., adsorption on settling particles; Figure 1).

Removal by scavenging can follow two distinct pathways (Anderson et al., 1990): a vertical pathway (proximal scavenging) due to rapid adsorption on particles settling locally and a lateral pathway (boundary scavenging) resulting from intensified scavenging at the ocean margins and other regions of high particle flux, following lateral transport (Figure 2). Partitioning between these two modes of removal is dictated by the residence time (or particle reactivity) of the scavenged element. Elements with lesser affinity for particles have longer residence time in the water column and can be transported laterally over longer distances to be preferentially removed by boundary scavenging in high particle flux regions. On the other hand, elements with very high affinity for particles have very short residence times in the water column, which limit the extent to which they can be laterally transported before removal. As a result, they tend to be removed locally by proximal scavenging (Bacon, 1988).

Thorium is among the most particle-reactive elements and is thus rapidly removed from the water column, primarily by proximal scavenging. The activity of ^{230}Th in seawater increases with depth from $<0.1 \text{ dpm m}^{-3}$ in surface water to $\approx 1 \text{ dpm m}^{-3}$ at the bottom of the ocean (Francois, 2007). This is nearly four orders of magnitude lower than the activity of its

Figure 2 Proximal versus boundary scavenging. Elements with high affinity for particles are quickly removed from seawater by proximal scavenging. Elements with lesser affinity and longer residence times in seawater travel laterally over long distances to be preferentially removed in areas of high particle flux. Lateral transport occurs as a result of deep water circulation or eddy diffusion (see text for further explanations).

parent ^{234}U . The activity of ^{230}Th drops to much lower levels than the activity of ^{234}Th discussed above because the half-life of ^{230}Th is much longer (75.38 ka). With such a slow decay rate, ^{230}Th is overwhelmingly removed by scavenging rather than decay, even in deep waters where scavenging intensity is relatively weak.

The residence time of ^{230}Th in the water column (τ_{Th}) can be estimated by comparing its activity in seawater ($^{\text{sw}}A_{\text{Th-230}}$) to that of its parent ^{234}U ($^{\text{sw}}A_{\text{U-234}}$). Equation [3] indicates that the rate of removal of ^{230}Th (atoms min^{-1}) is equal to the activity of ^{234}U minus that of ^{230}Th . The residence time of ^{230}Th in seawater (τ_{Th}) with respect to scavenging is equal to the number of atoms of ^{230}Th present in seawater ($^{\text{sw}}A_{\text{Th-230}}/\lambda_{230}$) divided by their rate of removal by scavenging ($R_{\text{Th-230}}$). Therefore,

$$\tau_{\text{Th}} = ^{\text{sw}}A_{\text{Th-230}}/(\lambda_{230} \times R_{\text{Th-230}}) \quad [9]$$

$$\tau_{\text{Th}} = ^{\text{sw}}A_{\text{Th-230}}/(\lambda_{230} \times (^{\text{sw}}A_{\text{Th-234}} - ^{\text{sw}}A_{\text{Th-230}})) \quad [10]$$

$$\text{Since } ^{\text{sw}}A_{\text{Th-230}} \ll ^{\text{sw}}A_{\text{U-234}}$$

$$\tau_{\text{Th}} \cong ^{\text{sw}}A_{\text{Th-230}}/(\lambda_{230} \times ^{\text{sw}}A_{\text{U-234}}) \quad [11]$$

With a ^{234}U activity of 2910 dpm m^{-3} and a range from <0.1 to 1 dpm m^{-3} for ^{230}Th , the residence time of the latter in seawater thus ranges from <4 years in the upper water column to ≈ 40 years in deep water. Since the time required for lateral transport in a typical ocean basin is ≈ 100 years (Anderson et al., 1990), such short residence times indicate that removal of ^{230}Th by boundary scavenging is very limited, and thus ^{230}Th removal from the water column occurs primarily via the proximal route. This has been confirmed in modeling studies (Henderson et al., 1999; Siddall et al., 2008) and by direct measurements of the settling flux of ^{230}Th in the ocean (Yu et al., 2001).

An important paleoceanographic application has emerged from the rapid removal of ^{230}Th by proximal scavenging (François et al., 2004). To better understand past oceanic processes, paleoceanographers need to know the vertical rain rate

Figure 3 Estimating mass accumulation rates of sediments on the seafloor (see text for explanations).

Figure 4 Sediment redistribution on the seafloor after initial deposition results in mass accumulation rates (MAR) that are different from the vertical rain rate of particles originating from the overlying surface waters.

of particles originating from surface waters, which can be interpreted in terms of export production of biogenic material or rates of supply of lithogenic particles from continents. Traditionally, this information is obtained by calculating mass accumulation rates (MARs) of sedimentary constituents on the seafloor (Figure 3). Sediment cores are taken from the seafloor and sediment subsamples are dated (mostly using ^{14}C or oxygen isotope stratigraphy; see Chapter [Oxygen Isotope Composition of Seawater](#)). The dates and depths of the subsamples within the sediment column provide sedimentation rates (cm year^{-1}) between dated horizons ($= (z_{i+1} - z_i) / (t_{i+1} - t_i)$; Figure 3). Total MARs ($\text{g cm}^{-2} \text{ year}^{-1}$) are then obtained by multiplying sedimentation rates by the dry bulk density (g cm^{-3}) of the sediment (i.e., the dry weight of 1 cm^3 of wet sediment) and the accumulation rates of any sedimentary constituent can be calculated by multiplying these MARs by the weight fraction of this sedimentary constituent.

A major problem with this approach, however, is that once settling particles reach the seafloor they are often redistributed (Figure 4) either by bottom currents that erode them from their initial sites of deposition and transport them to more quiescent areas of the seafloor, or by downslope transport, if they are initially deposited on sloping surfaces (François et al., 2004). As a result, MAR on the seafloor often bears little

resemblance to the initial rain rates from the overlying surface water, which is the information that is needed to address key paleoceanographic questions such as the changes in export fluxes of biogenic materials from surface to deep water or changes in supply rates of continental dust carried by winds to the ocean surface.

^{230}Th provides a solution to this problem (Bacon, 1984). Since the rate of production of ^{230}Th per m^3 of seawater is constant and well known (eqn [8]), we can easily calculate the rate of ^{230}Th production over the entire water column overlying the seafloor per unit surface area by simply multiplying $\beta_{\text{Th-230}}$ by the water-column depth (z):

$$P_{\text{Th-230}} = \beta_{\text{Th-230}} \times z \text{ (dpm m}^{-2}\text{year}^{-1}) \quad [12]$$

We have seen that because of its very short residence time in seawater, practically all the ^{230}Th that is produced in seawater by ^{234}U decay is removed vertically by proximal scavenging into the underlying sediment. Therefore, the vertical flux of scavenged ^{230}Th reaching the seafloor ($^vF_{\text{Th-230}}$) is always nearly equal to its known rate of production in the overlying water ($P_{\text{Th-230}}$). A small fraction of ^{230}Th is removed laterally by boundary scavenging, but this can generally be neglected (Yu et al., 2001). As a result, there is a simple inverse relationship between vertical flux of settling particles reaching the seafloor (vF_p) and the ^{230}Th concentration or activity in this settling material ($^pA_{\text{Th-230}}$; Figure 5):

$$^vF_p = ^vF_{\text{Th-230}} / ^pA_{\text{Th-230}} \approx P_{\text{Th-230}} / ^pA_{\text{Th-230}} \quad [13]$$

Downcore variations in the ^{230}Th activity measured in sediment (decay corrected to the time of deposition using ^{14}C or oxygen isotopes core chronology to take into account ^{230}Th decay during burial) thus provide estimates of past changes in the vertical flux of particles that reached the seafloor and accurate information on past changes in biological productivity in the overlying surface water or supply rates of mineral dust. In instances of sediment redistribution after initial deposition, since particles and adsorbed ^{230}Th are redistributed together, the ^{230}Th activity in sediments is not affected, keeping the information on vertical rain rate intact.

Figure 5 Principle of ^{230}Th -normalization to reconstruct past changes in vertical rain rates of particles to the seafloor (see text for explanations).

Application of this simple approach has revealed the widespread occurrence of sediment redistribution on the seafloor and the often erroneous estimates of particle rain rates based on sediment mass accumulation (François et al., 2004).

Paleoceanographic Applications Based on ^{231}Pa Activities in Marine Sediments

^{231}Pa is also produced uniformly in seawater but from the decay of ^{235}U (Table 1):

$$\beta_{\text{Pa-231}} = \lambda_{231} \times ^{\text{sw}}A_{\text{U-235}} \quad [14]$$

$$\beta_{\text{Pa-231}} = 2.17 \times 10^{-5} \text{ year}^{-1} \times 117 \text{ dpm m}^{-3} \quad [15]$$

$$\beta_{\text{Pa-231}} = 0.00247 \text{ dpm m}^{-3} \text{ year}^{-1} \quad [16]$$

Combining eqns [8] and [16], ^{231}Pa and ^{230}Th are produced at a constant ratio of

$$\beta_{\text{Pa-231}} / \beta_{\text{Th-230}} = 0.093 \quad [17]$$

Like thorium, protactinium is insoluble and is rapidly adsorbed on settling particles. It is, however, less particle reactive, resulting in a residence time in seawater that is about five times longer than that of thorium (Bacon, 1988). As a result, ^{231}Pa can be laterally transported over longer distances to be preferentially removed by boundary scavenging in regions of high particle scavenging where sediments are imparted a $^{231}\text{Pa}/^{230}\text{Th}$ ratio higher than 0.093 (Figure 6). This fractionation between the two radioisotopes during removal by scavenging and the resulting variations in sediment $^{231}\text{Pa}/^{230}\text{Th}$ ratios have seen distinct paleoceanographic applications in the Pacific and Atlantic Ocean. Differences in applications in these two oceans arise from different modes of lateral transport of ^{231}Pa .

$^{231}\text{Pa}/^{230}\text{Th}$ in Atlantic Sediments

The rate of the Atlantic meridional overturning circulation (MOC) (see Chapter [Late Pleistocene North Atlantic](#)) is the main factor controlling sediment $^{231}\text{Pa}/^{230}\text{Th}$ in the sediment deposited in the Atlantic (Yu et al., 1996; Luo et al., 2010). The Gulf Stream carries warm saline water from the subtropical regions to the northern Atlantic. As this water cools by transferring heat to the atmosphere, its density increases and it eventually sinks to produce a deep-water mass known as the North Atlantic Deep Water (NADW), which transits through the entire Atlantic basin to emerge in the Southern Ocean, from where it fills the deep basins of the Indian and Pacific Ocean (Broecker, 1991). The heat brought to high northern latitudes ameliorates the climate of northern continental masses and is implicated in the large and abrupt climate changes that characterize the Quaternary period (see Chapter [Late Pleistocene North Atlantic](#)). $^{231}\text{Pa}/^{230}\text{Th}$ in Atlantic sediments thus provides a tool to reconstruct past changes in the rate of MOC in relation to climate changes.

In the modern ocean, the residence time of ^{231}Pa in seawater is equivalent to the transit time of NADW through the Atlantic (Figure 7). As a result, nearly 50% of the ^{231}Pa produced in the NADW during its transit is exported to the

Figure 6 Fractionation between ^{230}Th and ^{231}Pa during their removal from seawater by particle scavenging. ^{230}Th and ^{231}Pa are produced at a constant rate (P_{Th} and P_{Pa}) and uniform rate ratio (0.093) in seawater. ^{230}Th has a shorter residence time in seawater limiting horizontal transport (H_{Th}). ^{230}Th is thus mainly removed by proximal scavenging and its vertical flux (V_{Th}) is always nearly equal to its production rate (P_{Th}). ^{231}Pa has a longer residence time resulting in lateral transport of ^{231}Pa (H_{Pa}) from regions with low scavenging intensity to regions of high scavenging intensity. As a result, the vertical flux of ^{231}Pa (V_{Pa}) is higher than its production rate in the overlying water column (P_{Pa}) in high flux regions, while it is lower in low flux region. Settling particles and sediments have thus a $^{231}\text{Pa}/^{230}\text{Th}$ activity ratio that is higher than the production rate ratio (0.093) in high flux regions and lower in low flux regions.

Figure 7 Principle for estimating the rate of the Atlantic meridional overturning circulation (MOC) from $^{231}\text{Pa}/^{230}\text{Th}$ in Atlantic sediments. ^{231}Pa and ^{230}Th are produced uniformly in seawater at a production rate ratio ($\beta_{\text{Pa}}/\beta_{\text{Th}}$) of 0.093. Because of its shorter residence time in the water column, nearly all the ^{230}Th produced in the North Atlantic Deep Water (NADW) during transit through the Atlantic is removed in the underlying sediment. On the other hand, since the residence time of ^{231}Pa in seawater is similar to today's residence time of deep water in the Atlantic, approximately half of the ^{231}Pa produced in the Atlantic is exported into the Southern Ocean with NADW resulting in a deficit of ^{231}Pa in Atlantic sediment. Surface sediment $^{231}\text{Pa}/^{230}\text{Th}$ increases with decreasing rate of NADW formation and export to the Southern Ocean.

Southern Ocean. On the other hand, because of its much shorter residence time, most of the ^{230}Th is removed in the Atlantic sediment. Reflecting this differential export, the mean $^{231}\text{Pa}/^{230}\text{Th}$ of Atlantic sediments (mean activity ratio ≈ 0.05) is much lower than the ratio of the rate of production of the two radioisotopes in the water column (0.093). Should the rate of NADW formation and transit have decreased in the past, the extent of ^{231}Pa export to the Southern Ocean would have also diminished, resulting in higher $^{231}\text{Pa}/^{230}\text{Th}$ in Atlantic sediments (Marchal et al., 2000; Siddall et al., 2007). The interpretation of this proxy is complicated by changes in particle flux and composition, which must also be monitored when interpreting sediment $^{231}\text{Pa}/^{230}\text{Th}$.

A first high-resolution $^{231}\text{Pa}/^{230}\text{Th}$ profile was obtained from a core retrieved from the North Atlantic. It revealed large changes in sediment $^{231}\text{Pa}/^{230}\text{Th}$ coincident with climatic variability during the last deglaciation (McManus et al., 2004; Figure 8). This record confirmed the steady formation of NADW over the entire warm Holocene period at a rate similar to present ($^{231}\text{Pa}/^{230}\text{Th} \sim 0.055$), and also documented a rapid increase in $^{231}\text{Pa}/^{230}\text{Th}$ to values approaching the production rate ratio (0.093) between 17 500 and 15 000 years BP. This was taken to indicate that MOC had nearly ceased during that period (particle fluxes decreased during that time interval and cannot account for the observation), which coincides with a massive iceberg discharge known as Heinrich Event H1 (see section 24). Deep water formation in the North Atlantic resumed abruptly at 15 000 year BP, coinciding with a rapid

Figure 8 Changes in sediment $^{231}\text{Pa}/^{230}\text{Th}$ in the North Atlantic during the last 20,000 years (McManus et al., 2004). Top black line shows the oxygen isotopic composition of ice accumulating on Greenland and reflecting air temperature (higher $\delta^{18}\text{O}$ = warmer temperature). Bottom blue line shows $^{231}\text{Pa}/^{230}\text{Th}$ in sediment. Dashed line is the production rate ratio of ^{231}Pa and ^{230}Th in seawater (see text for discussion).

Figure 9 $^{231}\text{Pa}/^{230}\text{Th}$ measured in the Holocene and the Last Glacial Maximum section of 5 cores taken at different depths in the North Atlantic (Gherardi et al., 2009). The Holocene sections have high $^{231}\text{Pa}/^{230}\text{Th}$ at 2000 m depth and much lower ratios below, consistent with the rapid formation of deep water in the modern Atlantic Ocean. In contrast, $^{231}\text{Pa}/^{230}\text{Th}$ in the glacial sections are low at depth shallower than 3000 m and higher below, indicating that the glacial MOC was vigorous but restricted to the upper 3000 m of the water column.

warming (Bølling) and rise in sea level. The analysis of additional cores (Gherardi et al., 2009) confirmed that general evolution of the Atlantic deep water circulation during the last deglaciation. These additional data also indicated, that the MOC did not completely cease during H1. Cores taken at shallower depth indicate the presence of relatively weak but significant rate of overturning within the upper 2000m of the water column. Results from this study also showed a clear contrast in the geometry of the glacial and Holocene MOC (Fig. 9). While these data show the potential of the approach, recent modeling studies, however, also indicate that their quantitative interpretation will require a much larger database (Siddall et al., 2007; Luo et al., 2010).

$^{231}\text{Pa}/^{230}\text{Th}$ in Pacific Sediments

In the Pacific Ocean, ^{231}Pa is effectively removed by boundary scavenging, as it is transported laterally by eddy diffusion (Figure 2) from low particle flux regions in the central gyres of the ocean to high particle flux regions near continental margins and at the equator, where biological productivity is higher (Bacon, 1988). As a result, the distribution of surface sediment $^{231}\text{Pa}/^{230}\text{Th}$ mirrors the ocean color measured from satellite, which reflects the amount of chlorophyll present and the biological productivity of surface waters (Figures 10). Pacific sediment $^{231}\text{Pa}/^{230}\text{Th}$ therefore offers the possibility of mapping past changes in ocean productivity, an important factor that affects the level of atmospheric CO_2 and greenhouse warming. Downcore profiles suggest a significant decrease in biological productivity in regions of the equatorial Pacific during colder glacial periods (Pichat et al., 2004; Figure 11). Complications arise, however, in the quantitative interpretation of such profiles, as $^{231}\text{Pa}/^{230}\text{Th}$ at a given site is affected by particle flux in neighboring areas and by the chemical composition of the settling material (Chase et al., 2002). Recent studies have actually used sediment $^{231}\text{Pa}/^{230}\text{Th}$ in the sediment of the equatorial regions to assess past changes in the settling flux of opal, which has a particularly high affinity for ^{231}Pa (Bradt Miller et al., 2006).

Why is the Interpretation of Sediment $^{231}\text{Pa}/^{230}\text{Th}$ Different in the Atlantic and the Pacific?

This contrast stems from the different mechanisms that transport ^{231}Pa laterally in the two oceans (Yu et al., 2001). In the Atlantic Ocean, the lateral transport of ^{231}Pa is mostly controlled by the meridional overturning circulation (Figure 7), which rapidly 'flushes' a large fraction of the ^{231}Pa produced in the Atlantic into the Southern Ocean. In the Pacific Ocean, there is no deep-water formation at high northern latitudes. As a result, the ^{231}Pa produced in Pacific waters remains in this ocean basin and is removed in Pacific sediments. The contrast

Figure 10 Correspondence between surface sediment in the Eastern Equatorial Pacific and ocean color measured by satellites.

Figure 11 Sediment $^{231}\text{Pa}/^{230}\text{Th}$ in a core from the eastern equatorial Pacific (ODP 849) covering the last 85,000 years and showing lower values during the colder glacial periods highlighted in gray (Pichat et al., 2004).

in scavenging intensity between regions of low particle flux (central gyres) and high particle flux (ocean margins and equatorial upwelling) creates horizontal gradients in seawater ^{231}Pa concentration that drives a lateral flux of ^{231}Pa from low to high particle flux regions by eddy diffusion, a process known as boundary scavenging (Figure 6). Consequently, downcore changes in $^{231}\text{Pa}/^{230}\text{Th}$ recorded in Pacific sediments mostly reflect changes in the contrast in particle flux between low and high productivity regions of the Pacific. On the other hand, the effect of boundary scavenging in the Atlantic Ocean is limited.

This is because the transit time of deep water through this basin is too short for the establishment of the lateral concentration gradients needed to transport ^{231}Pa by eddy diffusion from the central gyres toward the Atlantic margins. Instead, downcore variations in $^{231}\text{Pa}/^{230}\text{Th}$ recorded in Atlantic sediments reflect mostly the rate at which ^{231}Pa is exported to the Southern Ocean as a result of the meridional overturning.

Conclusions

Radioisotopes provide important quantitative tools to address key paleoceanographic questions during the last Quaternary climatic cycle (Henderson and Anderson, 2003). In particular, ^{230}Th provides a means of accurately quantifying past changes in the rain rate of particles from surface waters, which in turn provides insights into the evolution of oceanic productivity (François et al., 2004), while $^{231}\text{Pa}/^{230}\text{Th}$ brings important constraints on past changes in ocean circulation and its impact on climate (McManus et al., 2004). Our understanding of the role of the ocean on global climate that results from the application of these versatile tools enables us to better predict the future evolution of climate in response to anthropogenic forcing.

This article is a revision of the previous edition article by T. P. Guilderson and D. K. Pak, volume 3, pp. 1766–1775, © 2007, Elsevier B.V.

Introduction

Temperature and salinity are two of the key properties of ocean water masses. The distribution of these two independent but related characteristics reflects the interplay of incoming solar radiation (insolation) and the uneven distribution of heat loss and gain by the ocean, with that of precipitation, evaporation, and the freezing and melting of ice. Temperature and salinity, to a large extent, determine the density of a parcel of water. Small differences in temperature and salinity can increase or decrease the density of a water parcel, which can lead to convection. Once removed from the surface of the ocean where 'local' changes in temperature and salinity can occur, the water parcel retains its distinct relationship between (potential) temperature and salinity. One can take advantage of this 'conservative' behavior where changes only occur as a result of mixing processes, to track the movement of water in the deep ocean (Figure 1). The distribution of density in the ocean is directly related to horizontal pressure gradients and thus geostrophic ocean currents (currents resulting from the balance between gravitational forces and the Coriolis effect). During the Quaternary when we have had systematic growth and decay of large land-based ice sheets, salinity has had to change. A quick scaling argument following that of Broecker and Peng (1982) is as follows: the modern ocean has a mean salinity of 34.7 psu (practical salinity units) and is on average 3500 m deep. During glacial maxima, sea level was on the order of ~ 120 m lower than present. Simple scaling of the loss of freshwater (3–4%) requires an average increase in salinity of a similar percentage or to ~ 35.9 psu. Because much of the deep ocean is of similar temperature, small changes in salinity have a large impact on density, yielding a potentially different distribution of water masses and control of the density-driven (thermohaline) ocean circulation. It is partly for this reason that reconstructions of past salinity are of interest to paleoceanographers.

What is salinity? At the simplest of all levels, salinity is the total amount of dissolved materials in seawater. It is not practical to evaporate seawater samples to dryness to determine the total dissolved materials, and some materials such as chlorides are lost during drying. A more complete definition was created by the International Council for the Exploration of the Sea, whereby salinity was defined as the 'total amount of solid materials in grams dissolved in 1 kg of seawater when all the carbonate has been converted to oxide, the bromine and iodine replaced by chlorine and all organic matter completely oxidized.' Again, this is a difficult measurement to make accurately. Taking advantage of the near-constant proportionality of the major salts in seawater, salinity was 'redefined' using chlorinity and a simple linear relation $S = 1.80655 \times \text{Cl}$, where chlorinity is 'the amount of silver required to precipitate completely the halogens in 0.3285234 kg of seawater' (Wooster et al., 1969). At about the same time, a relationship between salinity and conductivity was

also proposed. Conductivity measurements are relatively easy compared to the chemistry-based techniques and are accurate. The relationship between salinity and conductivity has been revised slightly, such that the practical salinity scale of 1978 is now the official definition, and knowing the conductivity, pressure, and *in situ* temperature allows salinity to be calculated (JPOTS, 1980; Millero, 1996). Surface salinities reflect the precipitation–evaporation freshwater balance and span the full range of potential values from 0 psu in freshwater rivers and coastal environments to 42 psu in regions of high evaporation such as the Red Sea. Interior ocean salinities do not vary as much: ~ 33.8 psu (Antarctic intermediate water) to ~ 36.5 psu (North Atlantic central water), with abyssal waters in general differing by less than 1 psu (Figure 2).

Reconstructing Past Salinity Variations (with an Emphasis on the Quaternary)

As paleoceanographers, there are several different approaches that can be utilized to reconstruct past variations in salinity. These can be grossly classified as 'biological' and 'chemical.' In the purely biological approach, one relates the distribution and relative abundance of certain species to salinity and makes an assumption that this empirical relationship has been the same in the past. The salinity gradients in the deep ocean are very small, so this approach has been mainly used to attempt to reconstruct surface salinity variations in the open ocean and changes in estuarine or coastal environments. A classic example of this approach is the work of Climate: Long-Range Investigation, Mapping, and Prediction researchers (e.g., Kipp, 1976) who related the distribution of planktonic Foraminifera in core-top sediments to seasonal and annual salinity. In this example, the relative abundances of the (26) species of planktonic Foraminifera are deconstructed using Q-mode factor analysis (e.g., Imbrie and Kipp, 1971) into major modes or factors which are then related to surface salinity observations using a multiple linear regression scheme. The empirically derived relationship between the major factors and salinity is then used as a model to estimate past surface salinity from planktonic Foraminifera census counts in sediment samples taken downcore and back through time (Figure 3).

How might one otherwise reconstruct past salinity variations and take advantage of other 'conventional' biogeochemical proxies? Are there relationships between elements or isotopes in the skeletons of, for example, carbonate fossils and salinity? Can one directly measure past salinity variations?

'Current' Methods of Reconstructing Past Salinity

Current methods of reconstructing past ocean salinity focus on using either direct measurements of past $\delta^{18}\text{O}$ water

Figure 1 Western Atlantic salinity (psu) profile as a function of latitude and depth (m) observed during the GEOSECS expedition.

Figure 2 Relationship between potential temperature ($^{\circ}\text{C}$), salinity (psu), and seawater potential density (σ_{θ} : kg m^{-3}). Representative values for the three main interior water masses in the Atlantic Basin are shown: Antarctic intermediate water (AAIW), Antarctic bottom water (AABW), and North Atlantic deep water (NADW).

(e.g., glacial pore-water $\delta^{18}\text{O}$) or independent paleotemperature proxies (e.g., alkenones, foraminiferal Mg/Ca , coral Sr/Ca , and faunal assemblages) to extract the past $\delta^{18}\text{O}$ water signal from the $\delta^{18}\text{O}$ carbonate record (e.g., Malaize and Caley, 2009). Pore-water chlorinity measurements can be used to directly estimate glacial salinity. The indirect methods using biogeochemical proxies have the advantage over the direct pore-water estimates by facilitating time series and having the

Figure 3 Transfer function-based surface salinity estimate from the Columbian Basin through marine isotope stage 6. Left vertical axis is depth downcore (meters) and corresponding carbonate (isotope) stage designations are provided. potential to document so-called abrupt climate change events at the submillennial to seasonal timescale. The reconstructed $\delta^{18}\text{O}$ water record can then be deconvolved into its ice volume and salinity components. For the sake of this article, we focus

Figure 4 (a) Mean annual $\delta^{18}\text{O}$ of precipitation as a function of latitude (°N) and altitude, an update using the IAEA ISOHIS database to figures originally reported in, for example, Rozanski et al. (1993) among others. (b) Cartoon schematic of the effect of a growing ice sheet on mean ocean $\delta^{18}\text{O}$.

on open ocean salinity changes, although additional methods of reconstructing estuarine and brackish water salinities are used. For example, the large salinity changes associated with brackish environments allow the use of faunal assemblage changes as direct salinity proxies, whereas in open ocean environments salinity changes are generally too subtle to cause large faunal changes. We focus particularly on combining Mg/Ca and $\delta^{18}\text{O}$ measurements in marine carbonates as a means to reconstruct open ocean glacial–interglacial $\delta^{18}\text{O}$ water (salinity) estimates. An analogous technique applied to reef-building hermatypic corals is the combination of Sr/Ca and $\delta^{18}\text{O}$ (cf. McCulloch et al., 1994; see corals, sclerosponges, and mollusks).

One begins with the consideration of the workhorse of paleoceanography: $\delta^{18}\text{O}$ thermometry. This is done because the direct estimates of salinity during the last glaciation provide a constraint on one of the primary factors in the $\delta^{18}\text{O}$ of marine carbonate, and thus, there is a need to have a common basis of understanding. The ratio of $^{18}\text{O}:^{16}\text{O}$ (expressed as $\delta^{18}\text{O}$) in biogenic carbonates has been exploited as a geochemical paleothermometer, since the pioneering work of Urey (1947) and Epstein et al. (1953 and references therein). Weber and Woodhead (1972) documented that the oxygen isotope temperature sensitivity of reef-building hermatypic corals is similar to that of the oxygen paleotemperature scale developed for mollusks (e.g., Epstein et al., 1953 and references therein), $\sim 0.21\text{‰}$ per °C. Similar comparisons have been made using Foraminifera (e.g., Bemis et al., 1998; Shackleton, 1974, among many). Thus, biogenic carbonate $\delta^{18}\text{O}$ is a function of temperature and variations in the oxygen isotopic composition of water (δw). To be complete, carbonate ion content and pH also exert a small effect (Spero et al., 1997). For this discussion, it is assumed that this is a minor effect. Most marine biogenic carbonate materials have a temperature sensitivity similar to that of inorganic carbonate.

So, what controls the oxygen isotopic composition of seawater, and does this relate back to salinity? On long geologic

timescales, water–rock interactions control the mean isotopic composition. On glacial–interglacial timescales, ^{18}O -depleted water is locked up in ice sheets leaving the ocean more enriched in ^{18}O . In a gross oversimplification, ^{18}O is heavier than its more abundant ^{16}O cousin, and as moisture travels from the evaporating sources of the ocean to the growing ice sheet, the ^{18}O rains out in precipitation, leaving the remaining vapor depleted or more negative (cf. Craig and Gordon, 1965; Rozanski et al., 1993; Figure 4); this is in addition to the lower vapor pressure of ^{18}O which yields a more negative (fewer H_2^{18}O than H_2^{16}O compared to the water source) vapor phase to begin with. Thus, during glacial periods when this high-latitude precipitation is locked up in ice sheets, the ocean has more ^{18}O in it than during interglacials or, if preferred, less ^{16}O , which leaves the ocean relatively ‘enriched’ in ^{18}O with a corresponding more positive $\delta^{18}\text{O}$ water. Even without growing ice sheets, high-latitude (and altitude) precipitation has a more negative $\delta^{18}\text{O}$ value, and as this water enters the ocean as freshwater with zero salinity, it yields a relationship between salinity and $\delta^{18}\text{O}$ water. Craig and Gordon (1965) proffered the first oceanwide or global surface salinity– $\delta^{18}\text{O}$ water relationship: $\sim 0.6\text{‰}$ for every salinity unit (Figure 5(a)). In actuality, the whole ocean salinity– $\delta^{18}\text{O}$ water relationship is the result of a series of regional relationships (Figure 5(b) and 5(c)) that reflect the local precipitation–evaporation balance, the input of river or glacial meltwater, and the ocean dynamics (e.g., Fairbanks et al., 1992; Schmidt et al., 1999). Local/regional surface water $\delta^{18}\text{O}$ water–salinity relations range by an order of magnitude from $\sim 0.2\text{‰}$ to $\sim 1.5\text{‰}$ per psu (Figure 5(c)). The deep ocean $\delta^{18}\text{O}$ water–salinity relationship is on the order of $\sim 1.5\text{‰}$ per psu (e.g., Craig and Gordon, 1965).

If one can independently determine or estimate temperature and the eustatic (global) ice volume component, these can be converted into $\delta^{18}\text{O}$ space and subtracted from the measured (biogenic) $\delta^{18}\text{O}$ carbonate. The residual $\delta^{18}\text{O}$ is an estimate of regional $\delta^{18}\text{O}$ water (salinity) variations. Implicitly, it

sediment pore waters and determined that the mean ocean was $\sim 1\text{‰}$ heavier during the Last Glacial Maximum. Over time via diffusive processes, pore-water $\delta^{18}\text{O}$ equilibrates with that of the overlying deep ocean. Thus, the change from full glacial conditions ~ 20 ka to the present interglacial is 'remembered' in the sediments. Combining measurements with a pore-water diffusion model allows the glacial condition to be reconstructed from the current pore-water $\delta^{18}\text{O}$ water profile. To do so, they compressed or squeezed the pore waters out of sediment and analyzed their oxygen isotopic composition. These results provide a direct measure of removing the whole ocean $\delta^{18}\text{O}$ water from marine carbonate $\delta^{18}\text{O}$ analyses. This change can then be partitioned as a function of sea level (time) over the last glacial cycle in a fashion similar to that proposed by Fairbanks and Matthews (1978) and Fairbanks (1989). It is generally assumed that this relation holds for previous Pleistocene glacial cycles and is insensitive to the oxygen isotope composition of Northern versus Southern Hemisphere ice sheets. Adkins et al. (2002) performed a more difficult suite of pore-water chlorinity measurements, thus providing for the first time a direct measure of salinity of the deep ocean during the Last Glacial Maximum. Adkins et al. confirmed that the deep ocean was significantly saltier 20 ka and that the deep ocean was significantly colder than present (Figure 6). Astonishingly, Adkins et al. measured waters from the deep Southern and Pacific oceans that are significantly more salty than our whole ocean glacial estimate of 35.9 psu. They determined that, unlike today when the saltiest deep water is formed in the North Atlantic, the Southern Ocean was saltier by a large margin. Adkins et al. correctly infer that brine rejection during sea ice formation played a much more dominant role in deep-water production. A corollary to this observation is that the pole-to-pole freshwater budget must

Figure 6 Last Glacial Maximum salinity (psu) and potential temperature ($^{\circ}\text{C}$) as estimated from pore-water chlorinity, $\delta^{18}\text{O}$ pore waters, and benthic foraminiferal $\delta^{18}\text{O}$ at four ODP core sites. The stippled regions represent propagated error ranges, and curved lines denote lines of potential density referenced to 4000 dbar (σ_4) during the Last Glacial Maximum. The arrows demark mean ocean salinity for present (~ 34.7) and during the glaciation (~ 35.9). Present-day values/estimates for the core locations are also shown (filled circles). Error ellipses for glacial values are demarked as stippled pattern. Redrawn from Adkins JF, McIntyre K, and Schrag DP (2002) The salinity, temperature, and ^{18}O of the glacial deep ocean. *Science* 298: 1789–1773.

have been very different than today. A very strong constraint on the mechanisms of formation and redistribution of deep water during the last glaciation would be a systematic basin-wide pore-water study similar to Adkins et al. to accurately constrain the geometry of glacial deep waters. This direct reconstruction of paleosalinity (through chlorinity) removes assumptions and complications due to nutrient chemistry implicit in other biogeochemical proxies such as $\delta^{13}\text{C}$ (Curry and Oppo, 2005 and references therein).

Combined Mg/Ca and $\delta^{18}\text{O}$

At present, the combination of Mg/Ca and $\delta^{18}\text{O}$ of Foraminifera (and ostracods) has the greatest potential for reconstruction of Quaternary salinity changes, and this combined method is beginning to be widely applied. Foraminiferal Mg/Ca provides an independent temperature estimate that can be used to extract the $\delta^{18}\text{O}$ water signal from the $\delta^{18}\text{O}$ carbonate record. Although there are a number of commonly used paleotemperature proxies, including alkenones, foraminiferal faunal assemblages, Mg/Ca of Foraminifera, and Sr/Ca of corals, all of which have their own advantages and disadvantages, as a salinity proxy, the combination of Mg/Ca and $\delta^{18}\text{O}$ has the advantage that both analyses are conducted on the same material (foraminiferal calcite), thus alleviating issues related to differences in seasonality, habitat, and ecology.

Mg/Ca Paleothermometry

Although the relationship between Mg and temperature in calcite has been recognized for many years, Mg paleothermometry did not come widely into use until the 1990s. Several early studies documented that magnesium was higher in Foraminifera shells precipitated in warmer waters (Bender et al., 1975; Savin and Douglas, 1973), although initial concerns about secondary effects precluded wide acceptance of the Mg/Ca proxy. However, studies of inorganic calcite precipitation demonstrated that magnesium incorporation is largely controlled by thermodynamics and indicated that Mg substitution into the calcite lattice takes an exponential form that can be described by the equation

$$\text{Mg/Ca} = b e^{mT}$$

where b is the preexponential constant, m is the exponential constant, and T is the temperature (Katz, 1973; Oomori et al., 1987).

Mg/Ca Temperature Calibration Equations

Since these early studies, work has focused on developing Mg temperature calibration equations for biogenic calcites (benthic and planktonic Foraminifera, ostracods, and mollusks) using culturing, sediment trap, and core-top material. Calibration equations derived from live culturing experiments of *Globigerinoides sacculifer*, *Orbulina universa*, *Globigerina bulloides*, and *Neoglobobulimina pachyderma* take an exponential form and indicate that these Foraminifera species all incorporate Mg at a rate of $\sim 10\%$ per $^{\circ}\text{C}$ (exponential constants vary between 0.085 and 0.102 (e.g., Lea et al., 1999; Mashiotto et al., 1999; Nürnberg

et al., 1996); and also varies in few planktonic foraminifer species (Eggins et al., 2003)). The pre-exponential constant, which determines the absolute temperature, ranges from 0.3 to 1.36, although all cultured species except *O. universa* fall in the range of 0.3–0.5. The reason for the large difference between *O. universa* and the other planktonic species is unknown, although *O. universa* is morphologically unique in its formation of a final spherical chamber. Mg paleothermometry errors are on the order of 1.0–1.4 °C. Core-top and sediment trap studies are in good agreement with the culturing equations, and these studies have extended the calibration equations to additional planktonic species (Anand et al., 2003; Elderfield and Ganssen, 2000). Although both tropical and temperate species have similar exponential constants, tropical species have lower preexponential constants than temperate and subpolar species (Figure 7).

The development of benthic foraminiferal calibration equations has lagged behind that of planktonic Foraminifera, in part due to the difficulty in culturing these species, and the acquisition of live (e.g., rose bengal stained) benthic Foraminifera from multicores or box cores with good sediment–water interfaces. Rosenthal et al. (1997) defined a calibration equation for the

epifaunal genus *Cibicidoides* between 5 °C and 18 °C, which was extended to bottom water temperatures (<3 °C) by Martin et al. (2002), yielding an exponential equation of

$$\text{Mg/Ca} = 0.85.11\text{BWT}$$

The standard error derived from the data set is 1.14 °C. A study of Mg/Ca in other species of benthic Foraminifera indicated that although several common species yielded results similar to that of *Cibicidoides*, the paleoceanographically important taxon *Uvigerina* apparently has a lower temperature sensitivity (Lear et al., 2002; Martin et al., 2002).

Mg/Ca paleothermometry has also been successfully applied to marine ostracods (Cronin et al., 2000; Dwyer et al., 1995). These small, benthic crustaceans secrete a calcite shell that incorporates Mg/Ca very similarly to Foraminifera (~9% per °C), although linear calibration equations have been applied (Dwyer et al., 1995).

Secondary Effects

Because paleoceanographers are interested in isolating small temperature differences, it is important to accurately identify temperature changes. In addition to the temperature effect, the most prominent secondary effect on Mg/Ca in biogenic calcites is dissolution. Mg/Ca in shell calcite decreases with increasing dissolution on the seafloor. The cause of Mg loss is as yet uncertain but may be due to uneven distribution of Mg in shells and higher solubility of Mg-rich shell components. For instance, studies have shown that species with gametogenic calcite crusts or certain types of shell ornamentation, such as *N. dutertrei* or *G. tumida*, respectively, are more susceptible to Mg loss (Brown and Elderfield, 1996; Rosenthal et al., 2000). In order to have confidence in the Mg/Ca proxy, it is necessary to either analyze only pristine shells, or quantify the amount of dissolution and its effect on the Mg/Ca ratio. Dekens et al. (2002) analyzed Mg/Ca in three different planktonic species along Pacific and Atlantic depth transects in order to quantify the percentage of Mg loss with depth increase, and developed dissolution-corrected calibration equations. For instance, for Pacific *G. ruber*, the calibration equation is adjusted by 5% per kilometer depth. An alternative approach is to estimate the amount of postdepositional dissolution by measuring average shell masses and normalizing Mg/Ca ratios accordingly (Rosenthal and Lohmann, 2002).

Foraminiferal culturing experiments have been performed to quantify the effects of salinity and pH on Mg/Ca. These studies indicate that although temperature is the dominant control, both salinity and pH exert a minor influence on shell Mg/Ca. For *G. bulloides* and *O. universa*, shell Mg/Ca decreases 6% per 0.1 pH unit. Salinity exerts a smaller influence of ~4‰ per psu on *O. universa* (Lea et al., 1999 and references therein).

What Are the Errors for Past Salinity Estimates Using Mg/Ca and $\delta^{18}\text{O}$?

It is important to recall that $\delta^{18}\text{O}$ carbonate has a temperature sensitivity on the order of ~0.21‰ per °C and that Mg/Ca temperature estimates have an error of at least 1.1–1.4 °C, that is, the Mg/Ca temperature error alone contributes at

Figure 7 A composite of planktonic Foraminifera temperature (°C) versus Mg/Ca (mmol mol⁻¹) 'calibrations.' Data from von Langen et al. (2005), cultured *N. pachyderma* (d.); Mashiotta TA, Lea DW, and Spero HJ (1999) Glacial–interglacial changes in Subantarctic sea surface temperature and $\delta^{18}\text{O}$ water using foraminiferal Mg. *Earth and Planetary Science Letters* 170: 417–432; Elderfield H and Ganssen G (2000) Past temperature and $\delta^{18}\text{O}$ of surface ocean waters inferred from foraminiferal Mg/Ca ratios. *Nature* 400: 442–445; Nürnberg (1995), Norwegian Sea *N. pachyderma* (s.); Nürnberg (1995), South Atlantic *N. pachyderma* (s.); Nürnberg D, et al. (1996) Assessing the reliability of magnesium in foraminiferal calcite as a proxy for water mass temperatures. *Geochimica et Cosmochimica Acta* 60: 803–814; Dekens P, Lea DW, Pak DK, and Spero HJ (2002) A core-top calibration of Mg/Ca in tropical foraminifera: Refining paleo-temperature estimation. *Geochimica Geophysica Geosystems* 8; Anand P, Elderfield H, and Conte MH (2003) Calibration of Mg/Ca thermometry in planktonic foraminifera from a sediment trap time series. *Paleoceanography* 18(2): 1050. <http://dx.doi.org/10.1029/2002PA000846>, 002003.

least $\pm 0.2\text{‰}$ error to our estimate of past $\delta^{18}\text{O}$ water. There is the implicit assumption that the observed salinity– $\delta^{18}\text{O}$ water relations are constant through time. Regions with steep salinity– $\delta^{18}\text{O}$ water relationships have correspondingly smaller errors in their salinity estimate. In regions that have a well-constrained salinity– $\delta^{18}\text{O}$ water relation, there is the potential to reconstruct salinity to on the order of ± 0.3 – 0.4 psu. Assumptions on whole ocean $\delta^{18}\text{O}$ water changes during the Quaternary add at least another 0.1‰ $\delta^{18}\text{O}$ water error. Thus, errors of past $\delta^{18}\text{O}$ water–salinity estimates vary in space and time (e.g., Rohling, 2007). In spite of limitations in estimating salinity from $\delta^{18}\text{O}$ water, it would be possible to reconstruct the monsoon variability based on the $\delta^{18}\text{O}$ water and salinity by using paired measurements of $\delta^{18}\text{O}$ and Mg/Ca in planktonic foraminifer species from the Arabian Sea (Govil and Naidu, 2010) and Atlantic Ocean (Weldeab et al., 2007).

Quaternary $\delta^{18}\text{O}$ Water Variations: An Example from the Tropical Pacific

As an example of the combined Mg/Ca and $\delta^{18}\text{O}$ technique, the work of Lea et al. (2002) from the equatorial Pacific is highlighted. The focus is first on TR163-19 (2°N , 91°W) near the Galapagos in the eastern Pacific (Figure 8). Oxygen isotope measurements of the surface-dwelling planktonic

Foraminifera *G. ruber* exhibit the characteristic ‘sawtooth’ pattern observed in most if not all Quaternary $\delta^{18}\text{O}$ profiles. The glacial–interglacial difference in $\delta^{18}\text{O}$ carbonate is $\sim 1.8\text{‰}$. Mg/Ca concentrations on the same species of planktonic Foraminifera are interpreted to reflect a glacial–interglacial SST difference on the order of $\sim 2.6^\circ\text{C}$. If we strictly interpret the Mg/Ca results as SST and convert the temperature difference into $\delta^{18}\text{O}$ space, we can then subtract the ‘SST’ signature from the observed $\delta^{18}\text{O}$ carbonate. This yields a predicted $\delta^{18}\text{O}$ water time series that includes glacial (eustatic) and local/regional $\delta^{18}\text{O}$ water differences. The difference during the Last Glacial Maximum is $\sim 1.2\text{‰}$ which, if the whole ocean were heavier by $\sim 1\text{‰}$, leaves $\sim 0.2\text{‰}$. If the glacial salinity– $\delta^{18}\text{O}$ water relationship were similar to today’s, this difference implies an ~ 1 psu increase (i.e., more salty), either by reduced rainfall or by a stronger influence of subtropical surface waters brought to the equator in the north equatorial current. Given the location of the core relative to the modern-day intertropical convergence zone (ITCZ), a southward displacement of the ITCZ would allow for more subtropical water to gain influence over the site. Clearly apparent in the time series is the fact that tropical SST leads $\delta^{18}\text{O}$ water by ~ 3 ka, particularly on transitions to interglacial periods.

Because of questions regarding the exact history of eustatic (glacial) $\delta^{18}\text{O}$ water and the lack of a standardized curve (where at least every use would be working with the same record), Lea et al. (2002) like many others do not explicitly

Figure 8 (a) TR163-19, eastern equatorial Pacific downcore *G. ruber* $\delta^{18}\text{O}$ (‰) – blue and Mg/Ca (mmol mol⁻¹) and SST (°C) estimate – red. (b) Deconvolved $\delta^{18}\text{O}$ water (‰) – blue and Mg/Ca-SST (°C) – red using the data of (a). Data from Lea et al. (2002).

Figure 9 A comparison of Quaternary (0–400 ka BP) planktonic Foraminifera surface $\delta^{18}\text{O}$ water (‰) reconstructions from the western (ODP 806; solid blue) and eastern (TR163-19; dotted red) equatorial Pacific. To minimize noise, the individual data were passed through a triangle filter, and data have not had a sea level $\delta^{18}\text{O}$ correction applied. Core-top $\delta^{18}\text{O}$ water estimates are consistent with modern-day observations. Redrawn from Lea DW, Martin PA, Pak DK, and Spero HJ (2002) Reconstructing a 350 ka history of sea level using planktonic Mg/Ca and oxygen isotope records from a Cocos Ridge core. *Quaternary Science Review* 21: 283–293.

subtract out an ice volume component. Instead, Lea et al. (2002) use a 'site-to-site' comparison with ODP 806, a core from the western equatorial (0° , 159°E) Pacific warm pool (Figure 9). The site-to-site comparison assumes that the ice volume signal is common in each record, and therefore, differences between the two $\delta^{18}\text{O}$ water records are a reflection of changes in local salinity ($\delta^{18}\text{O}$ water). In the western Pacific the $\delta^{18}\text{O}$ water glacial–interglacial amplitude is only $\sim 0.75\text{‰}$ and less than that expected due to ice volume. This observation requires that the surface waters overlying ODP 806 had a more negative $\delta^{18}\text{O}$ water than today and were likely fresher or less saline. In combination with the results from TR163-169, the ODP 806 results indicate a different surface water $\delta^{18}\text{O}$ water gradient in the tropical Pacific during glacials with the east being more positive (saltier) and the west being more negative (fresher). An additional feature in both records, and especially in that of ODP 806, is what appears to be a long-term secular trend in $\delta^{18}\text{O}$ water on the order of $\sim 0.1\text{‰}$ per ka. If not an artifact, such a trend could indicate a larger glacial sea level drop earlier in the record (i.e., marine isotope stage 12) and/or a change in the mean $\delta^{18}\text{O}$ of glacial ice.

Where do $\delta^{18}\text{O}$ water–salinity reconstructions stand? The signals that one would like to directly interpret are small, and there have been inconsistencies when one study applies a calibration from one lab to another set of results or species measured by a different technique. The observation of interlaboratory offsets has necessitated standardization of Mg/Ca techniques (cf. Rosenthal and Lohmann, 2002; Lea et al., 2002). Consistently applied error propagation is necessary so that one can gauge the validity of any single downcore result: ideally, we want to be able to interpret submillennial variability when the sedimentary-depositional environment allows us to. To remove the ice volume component from the estimated $\delta^{18}\text{O}$ water requires, at the very least, a common internationally agreed upon standard Quaternary sea level record and ice volume ($\delta^{18}\text{O}$) scaling.

This article is a revision of the previous edition article by S.R. Hemming, volume 3, pp. 1776–1785, © 2007, Elsevier B.V.

Introduction

Terrigenous sediments are the weathering products of rocks exposed at the Earth's surface. They are brought to the ocean by rivers, winds, and ice. Although substantially more sediment is transported to the ocean by rivers than winds, most is retained near margins. Most of the clays deposited in areas far away from the continents are delivered by winds (Kennett, 1982; Rea and Hovan, 1995), see also review in Kohfeld and Harrison (2001), particularly in the Pacific Ocean. In polar and subpolar regions, melting icebergs may also contribute a significant amount of ice-rafted detritus (IRD) (see [Glaciomarine Sediments and Ice-Rafted Debris](#)). Once shed from the continent, terrigenous sediments are subject almost exclusively to physical processes, most importantly, transport by ocean currents. Turbidity currents and other gravity flows bring sediments from the continental shelves and river deltas to the deep ocean, where they can be picked up and transported by bottom currents. Strong surface and intermediate level ocean currents are also important for sediment transport and redistribution in the oceans (e.g., Franzese et al., 2006; Kennett, 1982; Latimer et al., 2006; Petschick et al., 1996).

The ability of an ocean current to transport particles depends on the speed of the current relative to the settling velocity of the particles, which is proportional to grain size (Figure 1). Changes in flow speed (either spatial or temporal) will alter the transport capacity of a current and the grain size distribution of the underlying sediment. Grain size is, therefore, a useful proxy for flow speed and an important measure of bottom currents' relationship to climate variability (e.g., McCave and Hall, 2006). Grain size alone, however, cannot give us information about changes in flow direction or about the upper-level ocean circulation.

Tying a deep-sea sediment sample to its continental source region (provenance) can yield important information about the processes responsible for its transport and deposition, including important paleoclimate variables such as wind speed and direction, aridity, glacial activity, and both surface and deep ocean currents. The composition of a terrigenous sediment sample depends on many variables related to the lithology and age of the source rock, as well as the weathering and transport history of the resulting sediment. An important problem in sediment provenance studies is distinguishing between provenance and process controls on the final, observed sedimentary composition. This article gives an overview that outlines the potential of terrigenous sediments in paleoceanographic applications, specifically concerning their provenance (sources), weathering history, sorting (grain size distribution), and flux (see [Paleoceanography An Overview](#)).

Provenance (Lithologic Source)

As previously mentioned, the geochemical and mineralogical composition of a terrigenous sediment sample depends on the

lithology and age of the source rock, as well as the weathering and transport history of the resulting sediment. The primary signature, however, is determined by the initial bulk composition of the source rock (i.e., felsic vs. mafic), its age, and geologic history.

The Earth's crust is formed by partial melting and subsequent fractional crystallization of the upper mantle. During this process, elements are fractionated based on their compatibility within the mantle rocks, and minerals are formed according to their crystallization temperatures (Figure 2; Bowen, 1928). During partial melting, elements that are more incompatible will be enriched in the melts and depleted in the residual solids, while more compatible elements are enriched in the residual solids and depleted in the partial melts. During fractional crystallization, olivine or ultramafic minerals are the first to crystallize, followed by mafic minerals (pyroxene, amphibole, biotite, and plagioclase), and finally the felsic minerals (potassium feldspar, muscovite, and quartz) most common on the Earth's surface. As these minerals form, they leave the residual magma depleted in the elements which are incorporated in those minerals and enriched in incompatible elements. For example, olivine tends to concentrate Ni, pyroxenes concentrate Sc and Cr, and plagioclase feldspars concentrate Ca, Sr, and Eu (e.g., Albarede, 2003).

The continental crust is formed by fractional crystallization of enriched magmas, giving them felsic compositions with high $\text{SiO}_2/\text{Al}_2\text{O}_3$ and $\text{K}_2\text{O}/\text{Na}_2\text{O}$, enrichments of incompatible elements, such as the alkali and alkaline earth elements, especially the large-ion-lithophile elements (K, Rb, Cs, and Ba), over compatible trace elements, and depletions in Eu compared to its neighboring rare earth elements (REE). Oceanic crust is thought to be formed from the residual depleted upper mantle and, therefore, has a mafic mineral composition with low $\text{SiO}_2/\text{Al}_2\text{O}_3$ and $\text{K}_2\text{O}/\text{Na}_2\text{O}$, relatively high concentration of refractory elements such as Fe and Mg, enrichments in compatible trace elements (e.g., Ni, Cr, and Sc) over incompatible ones, and no significant Eu depletions (e.g., Albarede, 2003; Taylor and McLennan, 1985).

The differences in bulk mineralogical and major and trace element concentrations also translate into different isotopic signatures for more mafic, depleted sources versus more felsic, enriched sources. This is due to the chemical properties of the radioactive parent elements compared to the radiogenic daughter elements. For the Rb–Sr system, the parent isotope, rubidium (Rb) is more incompatible than the daughter Strontium (Sr), leading to a higher Rb/Sr in magma melts compared to residual solids. This translates into higher Rb/Sr in the igneous rocks that make up the bulk of the continental crust and lower Rb/Sr in the mantle and the mafic igneous rocks of the ocean crust. Over time, ^{87}Rb decays to ^{87}Sr ($t_{1/2} = 48.8 \text{ Ga}$), increasing the concentration of ^{87}Sr relative to the stable, non-radiogenic isotope ^{86}Sr . For a given age, felsic rocks will have

Figure 1 Hjulstrom's diagram, showing the critical current velocity required to move quartz grains on a flat, uniform bed at a water depth of 1 m as well as the minimum velocity required to sustain transport for sediments of varying sizes. Electrostatic cohesion increases the critical erosion velocities of small particles (clay and fine silt).

Figure 2 Bowen's reaction series; the relative order of crystallization of the common silicate minerals from a cooling magma (Bowen, 1928).

higher $^{87}\text{Sr}/^{86}\text{Sr}$ than mafic rocks, and for a given composition, $^{87}\text{Sr}/^{86}\text{Sr}$ increases with age. The Rb–Sr system is, therefore, extremely useful for discriminating among potential source areas with very different bulk chemistries (i.e., felsic vs. mafic) or very different ages. Conversely, for the Sm–Nd system, the parent isotope Samarium (Sm) is slightly less incompatible than the daughter neodymium (Nd), leading to a lower Sm/Nd in magma melts compared to residual solids. This translates into higher Sm/Nd in the upper continental crust and lower Sm/Nd in the mantle and ocean crust. Over time, ^{147}Sm decays to ^{143}Nd ($t_{1/2} = 106$ Ga), increasing the $^{143}\text{Nd}/^{144}\text{Nd}$. In this case, for a given age, felsic rocks will

have lower $^{143}\text{Nd}/^{144}\text{Nd}$ than mafic rocks. This leads to a gross negative correlation between Nd and Sr isotopes in terrigenous sediments (Figure 3). The Sm–Nd and Rb–Sr systems are most widely used for constraining the provenance of terrigenous marine sediments (e.g., Dasch, 1969; Franzese et al., 2006; Goldstein et al., 1984; Grousset and Biscaye, 2005; Grousset et al., 1988; Jones et al., 1994). Although less widely used to date, the U–Th–Pb, Lu–Hf, and K–Ar systems have also been shown to provide powerful provenance constraints. The commonality in these is that they are the radioactive decay products of parents with long half lives. They have different sensitivities depending on the different geochemical behaviors of the parents and daughters and on the rock types and geological history of the sources. Thus, they provide provenance constraints that are related to both the age and time-averaged geochemical characteristics of sedimentary sources.

Geologic age will most obviously affect a continental source rock in terms of its radiogenic isotopic composition. Geologic age can also be expressed in the mineralogical, major and trace element composition, as older rocks are more likely to have been involved in processes such as metamorphism, weathering, and crustal recycling (discussed further below). For example, metamorphism affects the composition when soluble elements are mobilized and, subsequently, lost from the host rock. Weathering also tends to release soluble elements, so old continental rocks tend to have high ratios of insoluble/soluble elements (e.g., Rb/Sr and Th/U Dasch, 1969; Goldstein and Jacobsen, 1988; McLennan and Taylor, 1980). These effects are magnified if they occur over many rock cycles, so sediments derived from old upper continental crust tend to have extended histories of metamorphism and weathering and a substantial component of recycled sedimentary rocks in their provenance.

Figure 3 Nd (reported as ϵ_{Nd} , which is the fractional deviation of $^{143}\text{Nd}/^{144}\text{Nd}$ from the bulk Earth value in parts per 10 000) versus Sr isotope variations in river sediments (Goldstein and Jacobsen, 1988) and deep-sea turbidites (Hemming and McLennan, 2001; McLennan et al., 1990). Although there is generally a negative correlation between these two isotopes, the range in $^{87}\text{Sr}/^{86}\text{Sr}$ for a given provenance is great, particularly for sediments of ancient (low ϵ_{Nd}) provenance.

Sedimentary Processes

In addition to provenance variability and mixing, the processes of weathering and transport can have significant impact on terrigenous sediment composition. During these processes, elements are fractionated based on their chemical behavior (soluble vs. insoluble or refractory) and the relative stability of their mineralogical host(s). Sediments are the byproduct of weathering; some of them are minerals altered from the original rock, some simply reduced in size, and some are newly formed minerals.

Physical weathering tends to break down softer minerals, leaving behind the hardest, most resistant minerals. Chemical weathering involves the breakdown of the primary minerals in the rock to new secondary minerals that are more stable in the surface environment or to material that may be carried away in solution. The stability of minerals can be predicted using Bowen's reaction series (Figure 2; Bowen, 1928). In general, mafic minerals, the first ones to crystallize from a magma, are the most unstable at the Earth's surface and quickest to weather because the surface is most different from the conditions under which they formed at equilibrium. Felsic minerals are much more stable because the conditions at the surface are much more similar to the conditions under which they formed. Quartz is the most stable of the common rock-forming minerals, while feldspars are readily converted to clay minerals. For this reason, the quartz/feldspar ratio of sediment is often used as an indicator of the extent of weathering, and/or the importance of an old, recycled provenance (e.g., Diekmann and Kuhn, 2002; Diekmann et al., 2000; Kuhn and Diekmann, 2002).

As minerals are broken down and/or converted to clay minerals, the relative behavior of the elements becomes important. Insoluble, or refractory, elements (e.g., Al, Th, and REE) are retained in the rock regolith or newly formed minerals, while soluble elements (e.g., alkali and alkaline earth

elements and U) are more likely to be removed from the system. Postweathering, sediment transport tends to separate the weathering products from the host rock, fractionating the minerals and elements accordingly. In addition, particles are sorted by grain size, with the larger grains from a given source rock containing the most resistant minerals.

Formation and Distribution of Clay Minerals

Away from continental slopes, clay minerals are the most widely distributed terrigenous components in pelagic marine sediments, and their occurrence and distribution are well reviewed by (Kennett, 1982) (see *Eolian Records, Deep-Sea Sediments*). Some clays are formed as weathering or alteration products of primary silicate minerals, and others are recycled from sedimentary sources. All clay minerals are very fine-grained due to their crystal structure. Four types of clays are dominantly found in marine sediments: chlorite, illite, kaolinite, and smectite. In most cases, chlorite and illite are primary minerals from the source, while kaolinite and smectite are newly formed alteration products. Mineral composition of the clays is related to a number of factors, including source rock type and weathering. Weathering in turn is controlled by relief, temperature, precipitation, and vegetation, and consequently, the different kinds of clay reflect the major soil types in the source areas (Gibbs, 1967). Most clays are carried to the ocean and deposited without being changed, and thus marine sediments contain clays that reflect the weathering process that produced them (e.g., Biscaye, 1965). Primary minerals such as chlorite and illite are relatively more abundant in colder climates, while kaolinite is characteristic of tropical zones (Figure 4). Smectite tends to be associated with distribution of volcanic sources. The fact that much illite is brought to the ocean as a primary mineral is supported by the survey of K/Ar ages by Hurley et al., 1963.

Figure 4 Map of kaolinite/chlorite distribution of the $<2\ \mu\text{m}$ terrigenous fraction of sediments from the Atlantic Ocean. Modified from Biscaye PE (1965) Mineralogy and sedimentation of recent deep-sea clay in Atlantic Ocean and adjacent seas and oceans. *Geological Society of America Bulletin* 76(7): 803–832.

Geochemical Signatures of Weathering

In addition to mineralogical changes, predictable bulk chemical changes occur during weathering, and the chemical index of alteration (CIA) has been established as a general guide to the degree of weathering (Nesbitt and Young, 1982). Using molecular proportions (and only considering CaO residing in silicate minerals rather than in phosphate and carbonate):

$$\text{CIA} = 100 \times \frac{\text{Al}_2\text{O}_3}{[\text{Al}_2\text{O}_3 + \text{K}_2\text{O} + \text{Na}_2\text{O} + \text{CaO}]}$$

For marine sediments, it is also necessary to make a correction on Na_2O for seawater salt (e.g., McLennan et al., 1990). On the CIA scale, unweathered igneous rocks have values of 50 or slightly below, while the most extreme residual clays have values of almost 100. Typical shales average about 70–75 (Figure 5). The bulk-rock chemistry is dominated by the conversion of feldspars or glass to clay minerals during weathering.

The contents of some trace elements in sediments are different from those of their sources due to sedimentary processes of weathering and sorting, and measurement of these may provide clues about the processes and pathways of sediment distribution. For example, during weathering, there is a substantial increase in the Rb/Sr ratio of most solid residues (e.g., Dasch, 1969). Rb tends to follow K and is enriched in K-feldspar and micas, whereas Sr tends to follow Ca and is enriched in plagioclase and pyroxene. Plagioclase and pyroxene are generally susceptible to chemical attack during weathering, and Sr is removed to the aqueous system. Rubidium's hosts have greater resistance to chemical weathering, and additionally, Rb released during weathering tends to follow Al and thus be retained in the solid system. This is because Rb^+ , a large alkali trace element, is more readily retained on exchange sites of clays than the smaller alkaline earth element, Sr^{2+} , which is more easily lost to aqueous solution. Thus, terrigenous sediments that are derived from highly weathered terrains

Figure 5 Ternary plot of Al_2O_3 (A), $\text{CaO} + \text{Na}_2\text{O}$ (CN), and K_2O (K) of the terrigenous silicate fraction of sediments. Chemical index of alteration (CIA) is a measure of the degree of chemical weathering. The terminology comes from (Nesbitt and Young, 1982) and is reviewed in (McLennan et al., 1990, 1993).

and/or sedimentary sources will tend to have high Rb/Sr ratios. Over time, this evolves into higher $^{87}\text{Sr}/^{86}\text{Sr}$. Recent enrichments in Rb relative to Sr will result in lower $^{87}\text{Sr}/^{86}\text{Sr}$ and thus younger Rb–Sr model ages, so in favorable cases, it is possible to distinguish recent weathering from old sedimentary sources in terrigenous marine sediments.

The $\text{K}_2\text{O}/\text{Na}_2\text{O}$ and $\text{K}_2\text{O}/\text{CaO}$ of solid residues of weathering are also increased. Additionally, the K–Ar system may be almost entirely reset during extreme weathering. This is because K^+ is retained on exchange sites of clays, analogous to Rb^+ , and Ar is a noble gas that is released to the atmosphere during the breakdown of feldspar. Accordingly, the CAI, Rb–Sr, and K–Ar systems are complementary approaches to study time-integrated weathering effects on terrigenous sediments. Because K is much more soluble than Al or Rb, the ratios $\text{Al}_2\text{O}_3/\text{K}_2\text{O}$ and Rb/K should also increase in the sediments with enhanced chemical weathering and the conversion of silicate minerals to clay. Similarly, U can be oxidized to U^{6+} and forms the highly stable species $(\text{UO}_2)^{2+}$, which is much more soluble than Th, so weathering tends to increase Th/U in the sediments. This phenomenon is most easily observed with old, recycled sedimentary sources, as U would be continually lost during successive cycles of weathering (e.g., McLennan and Taylor, 1980).

Sorting

The processes of sediment transport and deposition tend to sort sediments by grain size. Grain size distributions can provide compelling information about the transporting agent (wind, water, and ice) as well as the velocity of wind and water. For example, wind tends to carry fine-grained sediments, with average grain size decreasing with distance from source (e.g., Rea, 1994). Bottom currents act to move sediments their

paths along shaped by bathymetric boundaries. Drift deposits accumulate in association with the movement of these deep water boundary currents. Bottom currents tend to enrich drift deposits in silt ($2\text{--}63\ \mu\text{m}$) and clay ($<2\ \mu\text{m}$) sized sediment. Sortable silt (SS) is defined as the $10\text{--}63\ \mu\text{m}$ silt fraction, because below about $10\ \mu\text{m}$, particles tend to behave cohesively and may not be sorted by primary particle size (e.g., McCave and Hall, 2006). This is due primarily to the dominance of clay minerals in the finer sediment fraction but also to van der Waals forces becoming significant. In general, the mean grain size of SS mean is proportional to bottom current speed, as is the percentage of SS% in the total $<63\ \mu\text{m}$ terrigenous fraction (reviewed in McCave and Hall, 2006), and the ratio of silt/clay (e.g., Diekmann et al., 2003; Hall and McCave, 2000; Kuhn and Diekmann, 2002).

Particles of different grain sizes often have different mineral and geochemical compositions, so sedimentary sorting can alter the composition of sediments deposited in the deep sea. Grain size tends to correlate negatively with elements that are associated with clay minerals, such as Al, Rb, and Cs. Clay fractions will also generally contain higher Rb/Sr than the coarse fractions. This can be conceived simply by considering the main host of Rb and Sr in the clay fraction to be illite and in the silt and sand fractions to be feldspar. In the first order, there is a separation of these elements according to mineralogy such that Rb is mostly found in mica and Sr is mostly found in feldspar. This is the reason there tends to be higher $^{87}\text{Sr}/^{86}\text{Sr}$ in clays compared to sands.

Sorting also tends to separate denser minerals from the bulk sediment. Zr, Hf, and heavy REE are enriched in the heavy mineral fraction of sediments, particularly in zircon (ZrSiO_4), which is among the most robust minerals, surviving multiple sedimentary cycles, as well as high-grade metamorphism and even melting, and tend to be more abundant in coarser sediments (e.g., Albarede, 2003; Taylor and McLennan, 1985). The ratio Zr/Rb has also been used as proxy for grain size or degree of sorting, since Zr is heavily concentrated in the coarse sediment, while Rb tends to be concentrated in clay (Liu et al., 2006).

In summary, sorting during sediment transport is a process of unmixing, whereby grains of different sizes are physically separated from one another. Because the different grain size fractions tend to have different compositions, differential sorting can create spatial or temporal variability in sediment composition with no change in average provenance, only in the average grain size of particles being deposited.

Application of Terrigenous Sediments in Paleooceanography

Distinguishing Between Provenance and Process

Sediments are inherently mixtures of particles from various sources. It is rare to find deep-sea sediment with a single point source of terrigenous sediment (outside of a delta). The composition of terrigenous sediment, therefore, represents a mixture of the multiple end-member source compositions. Variations in terrigenous sediment composition can be caused by variations in the composition or flux of one or more of the

end-member sediment sources, transport mechanism, and/or by the sedimentary processes described above.

As mentioned previously, it can be difficult to distinguish recent weathering from an old, crustal provenance. A change in an index of chemical weathering measured on terrigenous seafloor sediments could theoretically be interpreted as: (1) a change in the intensity of continental weathering just prior to the time of deposition, (2) a change in average provenance between more juvenile and more chemically mature parent materials, or (3) a combination of both. As an example, a relative depletion in Sr could be the result of surficial Sr loss or of a provenance change between sources with differing lithologies. Strontium is a moderately incompatible element that is highly mobile during surficial weathering. Comparing Sr concentrations with those of other elements that are refractory in surficial processes but have different compatibilities in igneous systems should permit discrimination between lithologic variability and weathering. Nd, Th, and Y are all relatively insoluble; Nd has a similar compatibility to Sr; Th is more incompatible than Sr; and Y is much more compatible. Therefore, with provenance variability, lower Sr/Th should be accompanied by lower Nd/Th, and lower Sr/Y should be accompanied by lower Nd/Y. With chemical weathering, on the other hand, Sr/Th and Sr/Y should decrease with no change in Nd/Th or Nd/Y.

It is also possible to use trace element ratios to isolate source compositional variability from sedimentary sorting. For example, Th and Zr are both incompatible elements, while Sc is moderately compatible during melting and crystallization of magmas. In the absence of any sedimentary processes, the ratios Th/Sc and Zr/Sc should correlate (Figure 6). Because sorting does not appreciably separate Th from Sc, but sorting of zircons makes large differences in the Zr/Sc, any increase in Zr/Sc for relatively constant Th/Sc provides a clear indication of cases where substantial enrichment of zircon has occurred as a result of sorting (McLennan et al., 1990, 1993).

As described in previous sections, the Rb–Sr isotope system may be disturbed by many geological processes, some of which are part of the continental provenance, and others that may be related to recent weathering and transport processes. The Sm–Nd isotope system, on the other hand, provides an average age of crust formation of the sediment's sources (Goldstein et al., 1984). As reviewed by Taylor and McLennan (1985), this is because Sm and Nd are REE with similar radii and, thus, are generally not separated by most sedimentary processes (although there are exceptions). The Rb–Sr system thus provides a wide range of compositions for a given Sm–Nd model age or $^{143}\text{Nd}/^{144}\text{Nd}$ (Dasch, 1969; Goldstein and Jacobsen, 1988). Comparing variations in the two isotope systems is therefore a useful way to confirm whether Rb–Sr system changes are related to provenance or sedimentary process (e.g., Franzese et al., 2006; Revel et al., 1996a,b; Walter et al., 2000).

Grain size distributions can also provide valuable information on provenance and dispersal of sediments, especially when combined with geochemical data and inverse end-member modeling (e.g., Weltje and Prins, 2003). Such a combined approach of quantitative grain size and compositional variability can often discriminate between process-related changes (e.g., wind speed or current speed) and changes in sediment source or delivery mechanism (e.g., wind vs. ocean).

Figure 6 Th/Sc versus Zr/Sc. Th and Zr are both incompatible in igneous processes, while Sc is compatible. Accordingly, increasing ratios in source rocks indicate more evolved compositions. Because sorting does not appreciably separate Th from Sc, but sorting of zircons makes large differences in the Zr/Sc, increase in Zr/Sc for relatively constant Th/Sc provides a clear indication of cases where substantial enrichment of zircon has occurred as a result of sorting. Reproduced from McLennan SM, Taylor SR, McCulloch MT, and Maynard JB (1990) Geochemical and Nd–Sr isotopic composition of deep-sea turbidites – Crustal evolution and plate tectonic associations. *Geochimica et Cosmochimica Acta* 54(7): 2015–2050; McLennan SM, Hemming S, McDaniel DK, and Hanson GN (1993) Geochemical approaches to sedimentation, provenance, and tectonics. *Geological Society of America* 284: 21–40 (Special Paper).

Terrane Types or Components

Any compositional variability (in time or space) that cannot be explained by recent sedimentary processes must be due to provenance variations. In some cases, potential source areas can be identified and directly compared with the deep-sea sediment. In many cases, however, there are no unique ways of identifying or ‘fingerprinting’ sediment sources, and it is useful to group sediment provenance characteristic into terrane types. Five such groupings have been described extensively (McLennan et al., 1990, 1993); they are (1) old upper continental crust, (2) recycled sedimentary rocks, (3) young undifferentiated arc, (4) young differentiated arc, and (5) exotic components. A sixth component that may be a significant portion of the terrigenous marine sediments in the pelagic realm, and away from continental inputs (e.g., in the Antarctic Circumpolar current, downstream from oceanic plateaus and ridges) is (6) oceanic basalt. Continental crust is distinguished from undifferentiated sources (arc and oceanic basalt) by evolved major element compositions (e.g., high $\text{SiO}_2/\text{Al}_2\text{O}_3$ and $\text{K}_2\text{O}/\text{Na}_2\text{O}$), negative Eu anomalies, and enrichments of normally incompatible over compatible trace elements. For example, continental crust yields sediments with light REE enrichment, high Th/Sc, and high La/Sc.

Sediments derived from old upper continental crust tend to have a substantial component of recycled sedimentary rocks in their provenance. In addition to the characteristics generally noted for continental crust, sediments derived from old

continental crust will tend to have high Rb/Sr and high Th/U reflecting weathering and sedimentary recycling. The presence of old continental sources is most simply identified by radiogenic isotope analyses.

Recycled sedimentary rocks are a common and important contributor to terrigenous sediments, and it is difficult to distinguish ambient weathering from recycled sedimentary sources. Measurements such as K/Ar ages, Rb/Sr model ages, and clay mineralogy are probably the best ways to distinguish these in young terrigenous sediments.

Young undifferentiated arc sources are recently derived from the mantle without significant intracrustal differentiation. This provenance component has many attributes in common with oceanic basalt sources but may have different implications for sedimentary (and thus paleoclimate/paleoceanography) applications. In Quaternary applications, the distribution of possible sources is largely still available for study, and the geographic pattern of variation in provenance helps to distinguish these contributions. Compared to continental sources, they provide sediments with less evolved major element compositions (e.g., low but variable $\text{SiO}_2/\text{Al}_2\text{O}_3$ and $\text{K}_2\text{O}/\text{Na}_2\text{O}$), absence of negative Eu anomalies, and little enrichments of normally incompatible over compatible trace elements, so they have low Th/Sc and La/Sc smaller recycled sedimentary component, so their CIA and Rb/Sr are low.

Young differentiated arc sources have very similar characteristics to continental crust and can be thought of as young continental crust. In most cases, these sources also tend to be less weathered than old continental sources, with a smaller recycled sedimentary component, so their CIA and Rb/Sr are low.

In specific cases, identification of even minuscule amounts of certain exotic components can have very important application. McLennan et al. (1993) cite published examples of their utility for constraining the timing of approach of allochthonous terranes as well as identifying ocean crust components in modern forearc turbidites. If identified, exotic components can provide near-unique information for interpreting provenance of terrigenous sediments in Quaternary settings.

Unmixing and Interpreting Changes in Mixing Proportions (Fluxes)

Spatial or temporal variations in the provenance of terrigenous sediment can often be linked to paleoceanographic and/or climatic changes. Such variations, even when clearly identified as independent of recent sedimentary processes, should be interpreted with caution. Seafloor sediments are often mixtures of various end-members, each with their own provenance. Any change in the composition of the mixture could, therefore, be the result of (1) a change in the composition of one or more end-member sources due to recent weathering and/or sorting; (2) the addition or removal of a sedimentary source; or (3) a change in the flux of one or more end-members to the site. The two previous sections describe some ways in which the first two options can be evaluated. The third option can be evaluated by first identifying the various end-members and then applying a set of end-member mixing equations to the data. Depending on the number of end-members and the number of variables, these can be as simple as single algebraic equation or

a complex matrix of algorithms such as those used in end-member mixing algorithm, reviewed in Weltje and Prins (2003). In general, the mixing equations take the following form:

$$R_{\text{mix}}C_{\text{mix}} = \sum (R_n C_n f_n) \text{ and } C_{\text{mix}} = \sum (C_n f_n)$$

where R stands for the isotope ratio, C for the concentration, and f for the mixing fraction of each of n end-members.

An important caveat is that the mixing fractions must always add up to 1 (or 100%), so the mixing equations can only solve for the relative proportions of the end-members. For example, in a simple situation with two end-members, A and B, one cannot distinguish an increased contribution of A from a decreased contribution of B with compositional data alone. By multiplying the mixing fraction by the total mass accumulation rates (MAR) of terrigenous sediment, one can calculate end-member MARs and identify which end-member (or end-members) actually changed. Going one step further, the MAR may not always be directly related to changes in local sediment flux. Lateral advection of sediment at the sea floor, whether syndepositional or postdepositional, can produce major changes in terrigenous MAR (reviewed in Francois et al., 2004). When evaluating provenance changes in the context of transport pathways ocean circulation, this is an important parameter to consider.

Constant flux proxies provide important constraints on sedimentary redistribution in the ocean. Examples are $^{230}\text{Th}_{\text{xs}}$ (derived from radioactive decay of ^{234}U in the water column, e.g., Bacon, 1984; Henderson and Anderson, 2003; Francois et al., 2004) and ^3He (derived from interplanetary dust particles, e.g., Ozima et al., 1984). ^{230}Th is a constant flux proxy because thorium is highly particle reactive, and thus, it is quickly removed from the water column after forming by radioactive decay of ^{234}U which uniformly produces ^{230}Th in the water column at a known and constant rate. The ^3He content of marine sediments is a constant flux proxy because interplanetary dust particles rain to the Earth at approximately constant rates, and they have extremely high ^3He contents. Thus, they act like an isotope spike. The enhancement of sedimentation rate by advection is well-known on drift deposits, for example, Bermuda Rise. In fact, they are favored sites for paleoceanography research due to the high accumulation rates that provide great temporal resolution. This process is termed 'focusing,' and the 'focusing factor' is the ratio of accumulation rate from chronology to accumulation rate that would hold if only sediment settling vertically through the water column above the deposition site were deposited. However, geochemical proxies for constant flux have identified additional sites where the sediment morphology does not clearly indicate drift deposits, yet the vertical accumulation of sediments based on chronology of the sediments is greater than that estimated from the concentrations of constant flux proxies in the sediment.

In a recent example, geochemical data (isotope ratios and trace element concentrations) was used to identify three major end-member sources for the sediments deposited south of Africa and to calculate the fraction of each end-member that contributes to each sediment sample. ^{230}Th -normalized fluxes were then used to determine that the provenance changes were

due in part to a lower supply of sediment derived from the Agulhas Current during the Last Glacial Maximum about 20 ka (Franzese et al., 2006). This was the first study to combine provenance tracers with ^{230}Th -normalization, which together have great potential for tracing sediment transport and source history.

Tools

Petrography

The simplest tool used to study terrigenous sediment is the petrographic microscope. Petrographic studies allow for visual identification of major lithological components in the sand ($>63\ \mu\text{m}$) fraction, as well as potentially diagnostic minerals and/or rock types. This approach has been particularly useful for identifying sources of IRD in the ocean. For example, it was the first line of evidence used to infer the importance of Hudson Strait sources to the Heinrich layers, layers rich in IRD in the North Atlantic associated with major abrupt climate change (Bond et al., 1992, reviewed in Hemming, 2004). It was also used by Bond and Lotti (1995), as well as others afterwards, to examine the relative timing of different iceberg contributors in the North Atlantic. Petrographic studies of IRD can sometimes be used to identify IRD from specific ice sheets and thus be used to make inferences about the behavior of specific ice sheets during times of climate change and can also be used to trace the average path of the main surface currents in regions where icebergs and sea ice are produced.

IRD is composed of a large spectrum of grain sizes, ranging from clay to sand and gravel, but its presence is identified in marine sediments by the coarse fraction, because rafting is the only means of delivering coarse sediment to these regions (e.g., Ruddiman, 1977). The recognition of IRD allows paleoceanographers to study ice-sheet dynamics in the past, and its distribution indicates the flow of surface currents that carried the icebergs (Figure 7).

Mineralogy by X-Ray Diffraction

X-ray diffraction (XRD) is the primary, nondestructive tool for identifying the mineralogy of fine-grained terrigenous sediments. Every mineral has a characteristic XRD pattern whose 'fingerprint' can be matched against a database of known minerals. XRD data can be analyzed to determine the proportion (weight percent) of the different minerals present.

Clay mineralogy by XRD provides important information on weathering history of marine sediments (e.g., Biscaye, 1965). For example, the kaolinite/chlorite of the $<2\ \mu\text{m}$ fraction of surface sediments from the Atlantic Ocean gives an important first-order view of the sources and processes responsible for distributing sediments in the ocean (Figure 4). Mineralogy by XRD has become a widely used tool in paleoceanography to constrain weathering intensity as well as sources and transportation pathways.

Geographic variations in clay mineralogy can help to constrain sediment transportation processes. For example, Petschick et al. (1996) made a more detailed map of the clay mineral distribution in the South Atlantic Ocean than the one from Biscaye (1965). The summary map from Petschick et al. (1996) is shown in Figure 8(a), along with surface

contributions and deep current systems. An example of inherited 'tropical' signal is seen in the kaolinite-rich zone near the Filchner-Ronne Ice shelf. Although deep currents represent an important means of transporting sediment, for example, the tongue of chlorite-rich sediment in the western South Atlantic along the South American margin, comparison of the clay province boundaries with the distribution of surface currents in the South Atlantic (Figure 8(b)), the bathymetry of the South Atlantic (Figure 8(c)), and the July and January average winds (Figure 8(d) and 8(e)), it becomes clear that surface currents (and/or the winds that drive them) are also responsible for the first-order distribution of terrigenous sediments in the South Atlantic.

In combination with clay mineralogy, the relative proportions of quartz and feldspar measured by XRD have been used to distinguish old, weathered, or recycled terranes with high Qz/Fsp ratios from younger, fresher, or undifferentiated terranes (e.g., Diekmann and Kuhn, 2002; Diekmann et al., 2000; Kuhn and Diekmann, 2002).

Geochemistry

The combined provenance and transport history is expressed in the isotopic and major and trace element composition of the terrigenous sediment. Geochemical approaches, including isotopes, therefore, complement information inferred from mineralogical investigations. Although the composition of organic matter from terrigenous sources is acknowledged as a powerful provenance tracer, only the silicate portion of these sediments is reviewed here. Geochemical approaches to the silicate portion of terrigenous sediments allow us to constrain provenance age and geochemical history of the source as well as the weathering history. As described by McLennan et al. (1993), among the important geochemical characteristics that define fundamental provenance types are radiogenic isotope compositions (reflecting average provenance age), large-ion lithophile element enrichments, and other trace element characteristics such as Eu anomalies (reflecting provenance compositions), alkali and alkaline earth element depletions, and aluminum enrichment (reflecting weathering and alteration), Zr and Hf enrichments (reflecting increased concentration of zircon by sedimentary sorting), and high Cr abundances (indicating ultramafic sources).

Major and Trace Element Concentrations

Solution techniques

Paleoceanographic studies of terrigenous sediments use many of the same geochemical techniques commonly used to study rocks. In the case of deep-sea sediments, however, sequential leaching techniques are usually needed to remove biogenic and authigenic sediments prior to sediment digestion (e.g., Bayon et al., 2002). Major and trace element concentrations can then be analyzed in solution by inductively coupled plasma mass spectrometry (ICP-MS), optical emission spectroscopy (ICP-OES or ICP-AES), or atomic-absorption spectroscopy.

X-ray fluorescence

X-ray fluorescence (XRF) is a nondestructive technique used for chemical analysis of materials. An X-ray source is used to

Figure 7 Maps of IRD flux in the North Atlantic. Units are $\text{mg cm}^{-2} \text{ ka}^{-1}$ of terrigenous silicates in the $>63 \mu\text{m}$ fractions. (a) 125–115 ka, (b) 40–25 ka, (c) 25–13 ka (Last Glacial Maximum). The zone with Last Glacial Maximum flux of $>250 \text{ mg cm}^{-2} \text{ ka}^{-1}$ is shown on each panel for comparison purposes. Reproduced from Ruddiman WF (1977) Late quaternary deposition of ice-rafted sand in subpolar North-Atlantic (Lat. 40° to 65°N). *Geological Society of America Bulletin* 88(12): 1813–1827; Hemming SR (2004) Heinrich events: Massive late Pleistocene detritus layers of the North Atlantic and their global climate imprint. *Reviews of Geophysics* 42(1).

Figure 8 Maps of clay mineral distribution in the South Atlantic, along with regional deep currents and local, near-continent surface currents (a) (reproduced from [Petschick R, Kuhn G, and Franz G \(1996\)](#) Clay mineral distribution in surface sediments of the South Atlantic: Sources, transport, and relation to oceanography. *Marine Geology* 130: 203–229), surface currents in the South Atlantic (b) (reproduced from Open University Oceanography Course Team (1989) *Ocean Circulation*. Oxford/New York: Pergamon Press; Milton Keynes), bathymetry of the South Atlantic (c), January winds (d), and July winds (e) (reproduced from Open University Oceanography Course Team (1989) *Ocean Circulation*. Oxford/New York: Pergamon Press; Milton Keynes). The distribution of clay provinces in the South Atlantic appears to be controlled by a combination of surface and deep currents and possibly surface winds.

irradiate the specimen and to cause the elements in the specimen to emit (or fluoresce) their characteristic X-rays. XRF is particularly well-suited for investigations that involve bulk chemical analyses of major elements (Si, Ti, Al, Fe, Mn, Mg, Ca, Na, K, and P) and trace elements (in abundances >1 ppm; Ba, Ce, Co, Cr, Cu, Ga, La, Nb, Ni, Rb, Sc, Sr, Rh, U, V, Y, Zr, and Zn) in sediment. In most cases, the sample is ground to a fine powder, mixed with a chemical flux, and melted in a furnace to create a homogenous glass (often known as a fused bead) that can be analyzed and the abundances of the elements calculated. This type of analysis is limited to relatively large discrete samples, typically >1 g.

XRF scanners are part of emerging technology that allows rapid semiquantitative determination of elemental concentrations in marine sediments at resolutions down to 100 μm . This has important implications for high-resolution surveying of marine sediment cores. An important example is the recognition of greatly increased flux of terrigenous sediments based on the Fe/Ca ratio of sediments from the Brazil margin, at the approximate times of Heinrich Events (massive iceberg events in the North Atlantic), that correlated to rapid climate variability in many parts of the world (Arz et al., 1998; Hemming, 2004). Another fundamental example is the correlation of Ti concentrations, as a proxy for rainfall in the Cariaco Basin, with collapse of the Mayan civilization (Haug et al., 2003) used terrigenous sediment compositions to evaluate variations in rainfall in the source areas to the Cariaco Basin, South America. In this case, the bulk titanium content of undisturbed sediment reflects variations in riverine input and the hydrological cycle over northern tropical South America and ties drought to the collapse of the Mayan civilization. With recent efforts to better calibrate the data from XRF scanners to elemental concentrations (e.g., Böning et al., 2007; Weltje and Tjallingii, 2008) we should expect to see more widespread use of this technique in paleoceanography in the future.

Isotope Ratios

Isotope ratios are measured by MS, though the exact technique depends on the isotope system of interest. For provenance work, most methods involve sequential leaching, sediment digestion, and separation chemistry prior to analysis by MS. Common isotope systems such as Rb–Sr and Sm–Nd can be measured by multicollector ICP–MS or thermal ionization MS, while Ar–Ar requires a gas source MS. Constant flux proxies must be measured on bulk sediment samples; $^{230}\text{Th}_{\text{xs}}$ measurements are easily made by ICP–MS, while ^3He measurements require a special noble gas MS.

Grain Size Distributions

Grain size measurements can be made by separating a sample into different grain size fractions and recording the weight of each. Sand sized particles (>63 μm) can be sieved dry, while coarse silt (20–63 μm) must be wet sieved. Below 20 μm , fine silt can be further separated based on settling velocity according to Stokes' Law. Various devices are available for making more detailed measurements of grain size distributions, including SS mean and SS%, and these have been reviewed in detail (Bianchi et al., 1999; McCave and Hall, 2006; McCave et al.,

2006). The instruments of choice for the study of deep-sea sediments as proxies for current intensity are the Sedigraph, which uses X-ray scanning to measure the gravity-induced settling velocities of different size particles in a liquid with known properties and the Coulter counter, passes particles suspended in a weak electrolyte solution through small apertures, and electrically senses the volume of electrolyte displaced (Bianchi et al., 1999; McCave and Hall, 2006; McCave et al., 2006).

DEDICATIONS

The second edition of the Encyclopedia of Quaternary Science is dedicated to the memory of three outstanding scientists who have recently passed away: Russell Coope, Bill Watts, and Aleksis Dreimanis.

Russell Coope

G. Russell Coope (1930–2011) was essentially the founding father of Quaternary Entomology, having initiated the modern era of Quaternary insect fossil research in the late 1950s. Prior to that time, and going back to the nineteenth century, there had been a number of false starts and stops in this field. Previous researchers had assumed that any ice-age insect fossils they found would necessarily represent extinct taxa. This, as it turns out, was a completely false assumption. Beginning with the Late Pleistocene Upton Warren and Chelford sites, Russell was able to determine that fossil insects, especially beetles (Coleoptera) from Pleistocene deposits, represent extant species, albeit species that may live in dramatically different regions today than those where they lived in the past. For many years at the start of this endeavor, Russell was ‘a voice in the wilderness,’ having to convince colleagues in both the Quaternary sciences and modern Entomology that it is possible to identify ‘beetle bits’ (individual sclerites of beetle exoskeleton) to the species level, and that fossil beetle assemblages can yield reliable reconstructions of past environments. One of his greatest battles was to convince skeptical palynologists that the interstadial interval in what is now known as MIS 3, and another one toward the end of the last glaciation, were almost as warm as today, in spite of the fact that the vegetation cover represented in pollen records failed to register this. Likewise, Russell championed the idea that climate oscillations, particularly in the late glacial interval and early Holocene, were extremely rapid and dramatic: switching from full glacial to full interglacial conditions in a matter of decades, at most. Russell’s paleoclimate reconstructions were finally given full credence by the scientific community at large when the oxygen isotope records from Greenland ice cores began to be published, showing nearly the exact same amplitude and timing of climate change he had been publishing since the 1960s.

Russell’s research has had important implications for the field of zoogeography. On the basis of his work, we now know that insects respond to climate change chiefly by shifting their distributional ranges, so that they

Figure 1 Russell Coope at the Chelford quarry fossil site, August 1977. Photograph by Alan V. Morgan, used with permission.

track these changes through space. Through his tenacity and hard work, Russell was able to track down the modern ranges of beetle species he found in Pleistocene deposits to such remote locations as northeastern Siberia and the Tibetan Plateau (cold-adapted species), as well as North Africa and the Mediterranean islands (warm-adapted species).

Russell brought a level of curiosity and enthusiasm for natural history and all things scientific that was infectious. He was a brilliant lecturer and storyteller, holding his audiences practically spellbound. He trained many of the paleoentomologists who took the field forward in recent decades. His seemingly boundless energy kept him working and publishing papers, right up to the end of his life. He published more than 200 papers in his long career. He collaborated with dozens of other Quaternary scientists and was one of the first to appreciate and promote multidisciplinary studies of Pleistocene fossil sites. There is no doubt that his research and publishing legacies will continue to inspire future generations of paleoentomologists.

Bill Watts

William (Bill) A. Watts (1930–2010) was a towering figure in Quaternary paleoecology. He was a skilled botanist and ecologist and this was a secret to his success in unraveling the interglacial, late-glacial, and Holocene vegetation history not only in his native Ireland but also in the midwestern, the southeastern, and eastern USA, and in Italy. A major contribution was his reintroduction and development of quantitative plant macrofossil analysis. Macrofossils can often be identified to lower taxonomic levels than pollen, and Bill took full advantage of the complementarity of both methods. Thus, he was able to determine important features of vegetation history by identifying trees to species level and to illuminate the history of aquatic plants and local vegetational developments.

Figure 2 Photograph of Bill Watts, taken at Laguna de la Roya, Spain. Photograph by Fraser Mitchell, used with permission.

Bill always enjoyed fieldwork and microscope work, carrying out the latter in spare time left over from his job as Provost of Trinity College Dublin and his participation on committees dealing with hospitals and conservation in Ireland. Bill's quiet but intense enthusiasm and his great sense of humor added much to discussions, macrofossil identification sessions, and excursions with him. He and his work are inspirations to those who follow him.

Figure 3 Aleksis Dreimanis, photograph by Stephen Hicock.

Aleksis Dreimanis

Aleksis Dreimanis (1914–2011) was widely considered the world's foremost Quaternary glacial geologist in the 1970s and 80s. Aleksis was born in Latvia. While still an undergraduate at the University of Latvia, he published his first paper on the structural geology of deformed glacial deposits along the banks of the River Daugava – a study that he would return to and revise 60 years later. In 1944, Aleksis was conscripted as a military geologist by the Germans who occupied Latvia. For the next two years, he was separated from his family and forced to do strategic geological mapping in eastern Germany and northern Italy until the end of WWII, followed by internment in prisoner of war and displaced persons camps. In 1948, he escaped to London, England, where he met with the President of the University of Western Ontario who gave him a job in London, Canada (his family was able to join him the following year).

Over the next six decades at the University of Western Ontario, Aleksis ascended to the top of his discipline while gaining international recognition through landmark publications and inspired leadership on committees. His 1970s synthesis and definition of the Wisconsin Stage with Paul Karrow, Jan Terasmae, Dick Goldthwait, and Jane Forsyth became a world standard to which other records were compared. In 1989, he expanded this synthesis and introduced the conceptual till tetrahedron that showed the till continuum with end members occupying the corners of an inverted pyramid. He was among the first geologists to use radiocarbon dating, and he provided samples for inter-lab calibration. He was among the first to quantitatively study the relationship between till lithology and till formation, and to investigate how glacial transport and dynamics determine till texture, deformation, and rheologic states. Aleksis produced over 200 publications spanning eight decades and over a wide range of topics. Largely because of his influence, the study of till genesis and its relation to till properties and past glacial behavior has become a major focus of glacial geologic research in recent decades. The contribution and legacy that forms the body of work of Dreimanis will continue as a major benchmark within the diverse fields of scientific enquiry that are sometimes loosely referred to as 'glacial geology.'

FOREWORD

As with the publication of the first edition in 2007, the publication of the second edition of the *Encyclopedia of Quaternary Science* represents a landmark in the history of publishing in the field of Quaternary Science. Quaternary Science is a multidisciplinary endeavor which seeks to establish as detailed a picture as possible of the manifold environmental changes that have occurred during the most recent geological period, the Quaternary – an interval of time that spans the past 2.59 million years or the past 0.056% of geological time. It is a period of significant climate and environmental change and witnessed the widespread dispersal of our species, *Homo sapiens*, across the planet.

Since Louis Agassiz and Reverend William Buckland traipsed over parts of the Scottish landscape in 1840 in search of evidence of glaciation, a huge literature has emerged on the science of long-term climate and environmental change. Rapid technological advances in the late twentieth century and the proliferation of scientific journals, particularly in an era of electronic publishing, have resulted in an exponential growth and documentation of knowledge on the climate and environmental changes that have occurred during the Quaternary period. More recently, there has been an increasing public interest in applied Quaternary research as a framework for understanding the basis for recent climate changes and for understanding the nature and frequency of geological hazards and vexing issues such as soil erosion and land degradation, and the adverse effects of ocean water temperature increases and acidification on coral reef environments. In a similar manner, the likely magnitude of future sea-level rise and the associated impacts on coastal landscapes in the twenty-first century have attracted wide public interest. In this sense, Quaternary Science is very much on the political agenda and is a critically important subject to address issues of public concern.

The *Encyclopedia of Quaternary Science* edited by Scott Elias of Royal Holloway, University of London, UK, accordingly represents a particularly welcome addition to the literature. The encyclopedia presents an up-to-date and authoritative overview of Quaternary Science. The encyclopedia should enjoy a wide readership as the entries are presented in a very clear and easily readable style. The text of the articles is written at a level that allows undergraduate students to understand the material, while providing active researchers with a ready reference resource for information in the field. Each entry of up to 4000 words covers the salient points of each topic with very clear illustrations. A central theme that pervades the work is the importance of Quaternary Science in providing an historical context for assessing present environmental changes and as basis for modeling potential future changes.

The encyclopedia consists of four volumes in print form and is available electronically. All the entries have been updated and the text totals around 3,500,000 words. As a major reference work, the encyclopedia has a very wide coverage of topics within the Quaternary sciences reflecting the complex and interdisciplinary nature of the science. Each of the major sections begins with a general overview of the topic prepared by a leading expert in the field. The major sections, for example, examine the analytical methods commonly used in paleoenvironmental reconstructions to unravel in a forensic-like manner the nature of former environments and the tempo of environmental change. Accordingly, a great range of topics such as the former extent of ice cover and nature of Quaternary glaciations, the biological responses and resultant fossil records to fluctuating climate, the expansion and contraction of desert environments, and global and local changes in relative sea levels are examined. Other topics covered include dating techniques, Quaternary stratigraphy, fluvial environments, lake level studies, paleosols, paleobotany, ancient DNA, paleolimnology, vertebrate studies, insect fossil studies, paleoceanography, stable isotope studies, ice core records, and human evolution in the Quaternary. One of the new sections in the encyclopedia examines the application of Quaternary proxy evidence in forensic science. All sections provide a clear summary of the latest advances in the fields of research.

This is an outstanding work and the editors and the publisher are to be congratulated for producing an encyclopedia that cogently summarizes the current state of the science.

A handwritten signature in black ink, appearing to read 'C. Murray-Wallace', with a stylized flourish at the end.

INTRODUCTION

It has been my privilege to work with more than 420 leading Quaternary scientists in developing the second edition of the *Encyclopedia of Quaternary Science*. This team of writers and editors represents 28 countries in Europe, Asia, Africa, the Americas, Australia, and New Zealand. Starting with the first edition in 2006, I have had my finger on the pulse of Quaternary science, and this branch of science is truly pulsating! Information now comes from an incredible variety of disciplines: geochemistry, numerical modeling, history, vulcanology, paleobiology, nuclear physics, stratigraphy, sedimentology, climatology, anthropology, archaeology, glacial geology, soil science, ice-stream modeling – the list is staggering. This highly disparate group of people are bound together by one common thread: the desire to know the history of the planet during the last 2.6 million years – the time of the ice ages. For Quaternary scientists, this is a pressing need, not an idle curiosity. Any doubts about this statement can be easily dispelled by a consideration of the lengths to which many of them go to gather the necessary data. Some of them have worked for months in sub-zero temperatures on top of very high mountains, or near the center of polar ice sheets, collecting ice cores. Others have spent many weeks on some of the roughest seas in the world, drilling deep-sea sediment cores. Often the work is more mundane. An oxygen isotope curve for a lengthy marine sediment core represents thousands of hours of patiently picking tiny fossils from layer after layer of sediments, in order to obtain sufficient numbers of calcium carbonate shells to yield samples for isotopic analysis. A map showing proposed ice limits from the last glaciation represents thousands of hours of field mapping of glacial features by dozens of people. Why do all of these people devote their lives to this pursuit of knowledge? Does it really matter so much? The answer becomes clear when you step back and examine the topic of Quaternary science in its proper context.

The world we inhabit has largely been shaped by the events of the Quaternary. All the biological communities that exist today are the end product of a long series of species associations that came together in the past, largely driven by climatic change during the Pleistocene. We cannot properly understand the functioning of modern ecosystems without a solid knowledge of their history, any more than we can understand the plot of a long novel by reading just the final page. We are also living in a time of alarming climate changes. Even though the pace and intensity of some of these changes have not been seen in historical times, there were many rapid, large-scale climatic shifts in the Pleistocene. The best way to predict the effects of global warming on the planet's climate and ecosystems is to look at the history of similarly intense, rapid changes in the prehistoric past. The interval that is most relevant today is the most recent geologic period: the Quaternary. As human populations rise exponentially, increasing numbers of people are exposed to geologic hazards, such as earthquakes (and attendant tsunamis), and volcanic eruptions. These are short-lived events that take place only rarely in any one region. The interval between major events, such as volcanic eruptions, may be centuries or millennia. How do we come to grips with predicting the future likelihood of such erratic phenomena? Again, the answers come from piecing together the ancient history of such events, over many thousands of years.

The Quaternary has been the time when our own species came of age. The beginning of the Quaternary, roughly 2.6 million years ago, was about the time when the earliest member of our genus (*Homo*) first appeared in Africa. Pleistocene environments shaped the course of human evolution, culminating in anatomically modern *Homo sapiens* spreading from Africa throughout most of the world during the last glaciation. Even though human beings largely shape their own environments today, for the vast majority of our species' history, it has been the environment that has shaped us. Our direct ancestors' adaptations to environmental change are deeply ingrained in our genes. Thus, an understanding of the environmental conditions that shaped our species is critical to our understanding of humanity.

Quaternary science is a rapidly changing field, and the articles that appear in this encyclopedia reflect this. New dating techniques, such as cosmogenic nuclide dating, are revolutionizing our understanding of many earth surface processes. The ability to analyze increasingly smaller samples for radiocarbon and stable isotopes of oxygen and hydrogen means that we are gaining a level of precision in the reconstruction of past events that was unheard of just a few years ago. Stable isotope studies of air bubbles trapped in ice cores from Greenland and Antarctica have given Quaternary scientists an entirely new perspective on the rapidity and intensity of climatic change during the last glacial cycle and beyond. Likewise, the discovery of long sequences of annually laminated sediments in both marine and freshwater environments has provided a great leap forward in our ability to resolve the timing of environmental changes in nonpolar regions. The ability to extract and analyze ancient DNA sequences from Pleistocene fossils (both plants and animals) is revolutionizing the field of paleobiology. We are beginning to be able to trace the genetic lineages of a number of different organisms, from beetles to bison. In short, these are very exciting times to be a Quaternary scientist! While it is virtually impossible for any Quaternary researcher or student to keep abreast of all the new discoveries in this multifaceted science, this encyclopedia can be of great help. The articles contained here represent the state of the art in a huge variety of topics, and they offer the opportunity to dig deeper into their respective subjects by providing full citations of the most pertinent literature available. I invite you to come and explore the Quaternary Period in the pages that follow. It is a fascinating story.

HOW TO USE THE ENCYCLOPEDIA

The material in this encyclopedia is organized into two broad sections. At the start of Volume 1 are four *Introductory Articles* that serve as a broad introduction to the field. It is intended that these articles should serve as the first port of call for readers, to enable them to embark on any of the main entries without the need to consult other material beforehand.

Following the Introductory Articles, the main body of The Encyclopedia is arranged as a series of entries in alphabetical order. These entries fill the remainder of the volumes.

To help realize the full potential of the material in the Encyclopedia we have provided four features to help you find the topic of your choice: a contents list by subject; an alphabetical contents list; cross-references to other articles; and a full subject index.

1. Contents list by subject

Your first point of reference will probably be the contents list by subject. This list appears at the front of each volume, and groups the entries under subject headings describing the broad themes of Quaternary science. This will enable the reader to make quick connections between entries and to locate the entry of interest. Under each main section heading, you will find several subject areas and under each subject area is a list of those entries that covers aspects of that subject, together with the volume and page numbers on which these entries may be found.

2. Alphabetical contents list

The alphabetical contents list, which also appears at the front of each volume, lists the entries in the order in which they appear in the Encyclopedia. This list provides both the volume number and the page number of each entry.

You will find ‘dummy’ entries where obvious synonyms exist for entries or where we have grouped together related topics. Dummy entries appear in both the contents list and the body of the text.

Example

If you were attempting to locate material on *peat studies* via the alphabetical contents list:

PEAT STUDIES *see* PLANT MACROFOSSIL METHODS AND STUDIES: Mire and Peat Macros

The dummy entry directs you to the entry in which *peat* is covered.

If you were trying to locate the material by browsing through the text and you had looked up *Peat Studies*, then the following information would be provided in the dummy entry:

Peat Studies *see* PLANT MACROFOSSIL METHODS AND STUDIES: Mire and Peat Macros

3. Cross-references

All of the entries in the Encyclopedia have been extensively cross-referenced. The cross-references, which appear at the end of the entry, serve three different functions:

- i. To indicate if a topic is discussed in greater detail elsewhere.
- ii. To draw the reader’s attention to parallel discussions in other entries.
- iii. To indicate material that broadens the discussion.

Example

The following list of cross-references appear at the end of the entry GLACIAL LANDFORMS, ICE SHEETS | Growth and Decay

See also: **Introduction:** History of Quaternary Science; **Paleoclimate Reconstruction:** Sub-Milankovitch (DO/Heinrich) Events; **Glacial Climates:** Thermohaline Circulation; **Glaciation, Causes:** Astronomical Theory of Paleoclimates; **Paleoclimate Modeling:** Last Glacial Maximum GCMs; **Glaciations:** Overview; **Sea Level Studies:** Overview; Paleocceanography; **Ice Core Records:** Correlations Between Greenland and Antarctica.

Here you will find examples of all three functions of the cross-reference list: a topic discussed in greater detail elsewhere (e.g., **Paleoclimate Modeling:** Last Glacial Maximum GCMs), parallel discussion in other entries (e.g., **Glacial Climates:** Thermohaline Circulation), and reference to entries that broaden the discussion (e.g., **Glaciations:** Overview).

4. Index

The index provides you with the page number where the material is located. The index entries differentiate between material that is a whole entry, is part of an entry, or is data presented in a figure or a table. Detailed notes are provided on the opening page of the index.

5. Contributors

A full list of contributors is listed at the beginning of each volume.

CONTENTS LIST BY SUBJECT

Location references refer to the volume number and page number (separated by a colon)

Introduction and History of Science

INTRODUCTION | History of Quaternary Science, 1:1
INTRODUCTION | History of Dating Methods, 1:9
INTRODUCTION | Societal Relevance of Quaternary Research, 1:17
INTRODUCTION | Understanding Quaternary Climatic Change, 1:26

Paleoclimatology

Overview and Approaches

PALEOCLIMATE | Introduction, 3:87
PALEOCLIMATE RECONSTRUCTION | Approaches, 3:179

 GLACIATIONS | Middle Pleistocene Glaciations in the Southern Hemisphere, 2:187
 GLACIATIONS | Late Quaternary of Antarctica, 2:216
 GLACIATIONS | Late Quaternary in North America, 2:245
 GLACIATIONS | Late Quaternary in Highland Asia, 2:236
 GLACIATIONS | Late Quaternary of the Southwest Pacific Region, 2:202
 GLACIATIONS | Late Pleistocene in Eurasia, 2:224
 GLACIATIONS | Late Pleistocene in South America, 2:250
 GLACIATIONS | Late Pleistocene Glacial Events in Beringia, 2:191
 GLACIATIONS | Neoglaciation in Europe, 2:257
 GLACIATIONS | Neoglaciation in the American Cordilleras, 2:269

Sea Level Studies

SEA LEVEL STUDIES | Overview, 4:369
 SEA LEVEL STUDIES | Geomorphological Indicators, 4:377
 SEA LEVEL STUDIES | Coral Records of Relative Sea-Level Changes, 4:409
 SEA LEVEL STUDIES | Use of Cave Data in Sea-Level Reconstructions, 4:460
 SEA LEVEL STUDIES | Eustatic Sea-Level Changes – Glacial–Interglacial Cycles, 4:429
 SEA LEVEL STUDIES | Eustatic Sea-Level Changes Since the Last Glacial Maximum, 4:439

SEA LEVEL STUDIES | Isostasy: Glaciation-Induced Sea-Level Change, 4:452
SEA LEVEL STUDIES | Sedimentary Indicators of Relative Sea-Level Changes – High Energy, 4:385
SEA LEVEL STUDIES | Sedimentary Indicators of Relative Sea-Level Changes – Low Energy, 4:396
SEA LEVEL STUDIES | Microfossil-Based Reconstructions of Holocene Relative Sea-Level Change, 4:419
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Relative Sea-Level Changes in High Latitudes, 4:467
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Sea-Level Changes in Greenland, 4:481
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Relative Sea-Level Changes at Mid-Latitudes, 4:489
SEA-LEVELS, LATE QUATERNARY | Late Quaternary Relative Sea-Level Changes in the Tropics, 4:495
SEA-LEVELS, LATE QUATERNARY | Tectonics and Relative Sea-Level Change, 4:503

Paleosols and Wind-Blown Sediments

Paleosol Research

PALEOSOLS AND WIND-BLOWN SEDIMENTS | Overview, 3:357
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Nature of Paleosols, 3:367
LOESS DEPOSITS: ORIGINS AND PROPERTIES, 2:573
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Weathering Profiles, 3:392
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Soil Micromorphology, 3:381
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Soil Morphology in Quaternary Studies, 3:402
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Mineral Magnetic Analysis, 3:375
PALEOSOLS AND WIND-BLOWN SEDIMENTS | Biogeochemical Role of Dust in Quaternary Climate Cycles, 3:412

Dune Studies

DUNE FIELDS | High Latitudes, 1:597
DUNE FIELDS | Mid-Latitudes, 1:606
DUNE FIELDS | Low Latitudes, 1:623

Loess Studies

LOESS RECORDS | Central Asia, 2:585
LOESS RECORDS | China, 2:595
LOESS RECORDS | Europe, 2:606
LOESS RECORDS | North America, 2:620
LOESS RECORDS | South America, 2:629
EOLIAN RECORDS, DEEP-SEA SEDIMENTS, 1:637

Lake Level Studies

LAKE LEVEL STUDIES | Overview, 2:483
LAKE LEVEL STUDIES | Modeling, 2:558
LAKE LEVEL STUDIES | Africa during the Late Quaternary, 2:499
LAKE LEVEL STUDIES | Asia, 2:506
LAKE LEVEL STUDIES | Australia, 2:524
LAKE LEVEL STUDIES | Latin America, 2:531
LAKE LEVEL STUDIES | North America, 2:537
LAKE LEVEL STUDIES | West-Central-Europe, 2:549

Paleobotany

Overview

PALEOBOTANY | Overview of Terrestrial Pollen Data, 2:699

Pollen Studies

POLLEN ANALYSIS, PRINCIPLES, 3:794
POLLEN METHODS AND STUDIES | Use of Pollen as Climate Proxies, 3:805
POLLEN METHODS AND STUDIES | Surface Samples and Trapping, 3:839
POLLEN METHODS AND STUDIES | The Biome Approach to Reconstructing Past Vegetation, 3:861
POLLEN METHODS AND STUDIES | POLLSCAPE Model, 3:871
POLLEN METHODS AND STUDIES | Reconstructing Past Biodiversity Development, 3:816
POLLEN METHODS AND STUDIES | Numerical Analysis Methods, 3:821
POLLEN METHODS AND STUDIES | Changing Plant Distributions and Abundances, 3:854
POLLEN METHODS AND STUDIES | Stand-Scale Palynology, 3:846
PALEOBOTANY | Paleophytogeography, 2:730
POLLEN METHODS AND STUDIES | Databases and Their Application, 3:831

Charred Particle Analysis

PALEOBOTANY | Charred Particle Analyses, 2:716

Quaternary Pollen Records

POLLEN RECORDS, LAST INTERGLACIAL OF EUROPE, 4:1
POLLEN RECORDS, LATE PLEISTOCENE | Africa, 4:9
POLLEN RECORDS, LATE PLEISTOCENE | Australasia, 4:18
POLLEN RECORDS, LATE PLEISTOCENE | Northern Asia, 4:27

POLLEN RECORDS, LATE PLEISTOCENE | Northern North America, 4:39
 POLLEN RECORDS, LATE PLEISTOCENE | Western North America, 4:72
 POLLEN RECORDS, LATE PLEISTOCENE | South America, 4:52
 POLLEN RECORDS, LATE PLEISTOCENE | Middle and Late Pleistocene in Southern Europe, 4:63
 POLLEN RECORDS, POSTGLACIAL | Africa, 4:85
 POLLEN RECORDS, POSTGLACIAL | Australia and New Zealand, 4:104
 POLLEN RECORDS, POSTGLACIAL | Northeastern North America, 4:115
 POLLEN RECORDS, POSTGLACIAL | Northwestern North America, 4:124
 POLLEN RECORDS, POSTGLACIAL | Southeastern North America, 4:133
 POLLEN RECORDS, POSTGLACIAL | Southwestern North America, 4:142
 POLLEN RECORDS, POSTGLACIAL | South America, 4:156
 POLLEN RECORDS, POSTGLACIAL | Northern Asia, 4:164
 POLLEN RECORDS, POSTGLACIAL | Northern Europe, 4:173
 POLLEN RECORDS, POSTGLACIAL | Southern Europe, 4:179
 POLLEN METHODS AND STUDIES | Archaeological Applications, 3:880

Phytoliths

PHYTOLITHS, 3:582

Ancient Plant DNA

PALEOBOTANY | Ancient Plant DNA, 2:705

Plant Macrofossil Studies

PLANT MACROFOSSIL INTRODUCTION, 3:593
 PLANT MACROFOSSIL METHODS AND STUDIES | Surface Samples, Taphonomy, Representation, 3:684
 PLANT MACROFOSSIL METHODS AND STUDIES | Treeline Studies, 3:690
 PLANT MACROFOSSIL METHODS AND STUDIES | Megafossils, 3:621
 PLANT MACROFOSSIL METHODS AND STUDIES | Paleolimnological Applications, 3:657
 PLANT MACROFOSSIL METHODS AND STUDIES | CO₂ Reconstruction from Fossil Leaves, 3:613
 PLANT MACROFOSSIL METHODS AND STUDIES | Rodent Middens, 3:674

PLANT MACROFOSSIL METHODS AND STUDIES | Mire and Peat Macros, 3:637
 PLANT MACROFOSSIL METHODS AND STUDIES | Use in Environmental Archaeology, 3:699
 PLANT MACROFOSSIL METHODS AND STUDIES | Dendroarchaeology, 3:630
 PLANT MACROFOSSIL METHODS AND STUDIES | Validation of Pollen Studies, 3:725

Plant Macrofossil Records

PLANT MACROFOSSIL RECORDS | Arctic Eurasia, 3:733
 PLANT MACROFOSSIL RECORDS | Greenland, 3:760
 PLANT MACROFOSSIL RECORDS | Arctic North America, 3:746
 PLANT MACROFOSSIL RECORDS | Holocene North America, 3:768
 PLANT MACROFOSSIL RECORDS | Late Glacial Multidisciplinary Studies, 3:785

Diatom Studies

DIATOM INTRODUCTION, 1:471
 DIATOM METHODS | Data Interpretation, 1:489
 DIATOM RECORDS | North Atlantic and Arctic, 1:562
 DIATOM RECORDS | Pacific, 1:571
 DIATOM RECORDS | Antarctic Waters, 1:527
 DIATOM RECORDS | Diatom Fossil Records from Marine Laminated Sediments, 1:554
 DIATOM RECORDS | Freshwater Laminated Sequences, 1:540
 DIATOM RECORDS | Large Lakes, 1:546
 DIATOM METHODS | Salinity and Climate Reconstructions from Continental Lakes, 1:507
 DIATOM METHODS | $\delta^{18}\text{O}$ Records, 1:481
 PALEOBOTANY | Silicon Isotopes in Diatoms, 2:734
 DIATOM METHODS | Use in Archaeology, 1:516
 DIATOM METHODS | Diatomites: Their Formation, Distribution, and Uses, 1:501
 Structures and Applications of Biomarkers from Arctic Sea Ice Diatoms, 1:588

Paleolimnology

PALEOLIMNOLOGY | Overview of Paleolimnology, 3:259
 PALEOLIMNOLOGY | Lake Chemistry, 3:292
 PALEOLIMNOLOGY | Physical Properties of Lake Sediments, 3:300
 PALEOLIMNOLOGY | Cladocera, 3:271
 PALEOLIMNOLOGY | Freshwater Mollusks, 3:281

PALEOLIMNOLOGY | Contributions of
Paleolimnological Research to
Biogeography, 3:313
PALEOLIMNOLOGY | Pigment Studies, 3:326
PALEOLIMNOLOGY | Visible and Infrared
Spectroscopical Applications, 3:349
PALEOLIMNOLOGY | Multiproxy Approaches, 3:339

Vertebrate Studies

VERTEBRATE OVERVIEW, 4:590
VERTEBRATE RECORDS | Early Pleistocene, 4:599
VERTEBRATE RECORDS | Early and Middle
Pleistocene of Northern Eurasia, 4:605
VERTEBRATE RECORDS | Mid-Pleistocene of
Southern Asia, 4:651
VERTEBRATE RECORDS | Mid-Pleistocene of
Africa, 4:615
VERTEBRATE RECORDS | Mid-Pleistocene of
Australia, 4:621
VERTEBRATE RECORDS | Mid-Pleistocene of
Europe, 4:639
VERTEBRATE RECORDS | Mid-Pleistocene of
North America, 4:646
VERTEBRATE RECORDS | Late Pleistocene of
Africa, 4:664
VERTEBRATE RECORDS | Late Pleistocene of North
America, 4:673
VERTEBRATE RECORDS | Late Pleistocene of South
America, 4:680
VERTEBRATE RECORDS | Late Pleistocene of
Southeast Asia, 4:693
VERTEBRATE RECORDS | Late Pleistocene
Megafaunal Extinctions, 4:700
VERTEBRATE RECORDS | Late Pleistocene
Mummified Mammals, 4:713
VERTEBRATE STUDIES | Ancient DNA, 4:719
VERTEBRATE STUDIES | Speciation and
Evolutionary Trends in Quaternary
Vertebrates, 4:723
VERTEBRATE STUDIES | Dwarfing and Gigantism in
Quaternary Vertebrates, 4:733
VERTEBRATE STUDIES | Interactions with
Hominids, 4:748

Insect Fossil Studies

Beetle Studies

BEETLE RECORDS | Overview, 1:161
BEETLE RECORDS | Late Tertiary and Early
Quaternary Records, 1:173
BEETLE RECORDS | Middle Pleistocene of Western
Europe, 1:184

BEETLE RECORDS | Late Pleistocene of
Europe, 1:200
BEETLE RECORDS | Late Pleistocene of North
America, 1:221
BEETLE RECORDS | Late Pleistocene of South
America, 1:235
BEETLE RECORDS | Late Pleistocene of
Australia, 1:191
BEETLE RECORDS | Late Pleistocene of Northern
Asia, 1:255
BEETLE RECORDS | Late Pleistocene of Japan, 1:207
BEETLE RECORDS | Late Pleistocene of New
Zealand, 1:244
BEETLE RECORDS | Postglacial Europe, 1:274
BEETLE RECORDS | Postglacial North America, 1:282

Chironomid Studies

CHIRONOMID RECORDS | Chironomid
Overview, 1:355
CHIRONOMID RECORDS | Late Pleistocene of
Europe, 1:373
CHIRONOMID RECORDS | Africa, 1:361
CHIRONOMID RECORDS | Late Pleistocene of
Europe, 1:373
CHIRONOMID RECORDS | Postglacial
Europe, 1:386
CHIRONOMID RECORDS | Postglacial Southern
Hemisphere, 1:398

Oribatid Mite Studies

ORIBATID MITES, 2:680

Paleoceanography

Paleoceanographic Studies

PALEOCEANOGRAPHY | Paleoceanography An
Overview, 2:745
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Corals, Sclerosponges and Mollusks, 2:795
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Benthic Foraminifera, 2:765
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Planktic Foraminifera, 2:825
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Radiolarians and Silicoflagellates, 2:830
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Coccolithophores, 2:783
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Alkenone Paleothermometry Based on the
Haptophyte Algae, 2:755
PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Marine Diatoms, 2:816

PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Dinoflagellates, 2:800

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Terrigenous
Sediments, 2:941

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Oxygen Isotopic
Composition of Seawater, 2:915

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Oxygen-Isotope
Stratigraphy of the Oceans, 2:907

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Dissolution of Deep-Sea
Carbonates, 2:859

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Mg/Ca and Sr/Ca
Paleothermometry from Calcareous Marine
Fossils, 2:871

PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Temperature Proxies Census Counts, 2:841

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Salinity Proxies
 $\delta^{18}\text{O}$, 2:932

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Nutrient Proxies, 2:899

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Carbon Cycle
Proxies, 2:849

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Radioisotope
Proxies, 2:923

PALEOCEANOGRAPHY, BIOLOGICAL PROXIES |
Biomarkers Indicators of Past Climate, 2:775

PALEOCEANOGRAPHY, PHYSICAL AND
CHEMICAL PROXIES | Magnetic Proxies and
Susceptibility, 2:884

Paleoceanographic Records

PALEOCEANOGRAPHY, RECORDS | Early
Pleistocene, 3:1

PALEOCEANOGRAPHY, RECORDS | Late
Pleistocene North Atlantic, 3:9

PALEOCEANOGRAPHY, RECORDS | Late
Pleistocene South Atlantic, 3:18

PALEOCEANOGRAPHY, RECORDS | Late
Pleistocene North Pacific, 3:33

PALEOCEANOGRAPHY, RECORDS | Postglacial
North Atlantic, 3:55

PALEOCEANOGRAPHY, RECORDS | Postglacial
North Pacific, 3:62

Introduction

From about 3 My ago to now, the climate of the Earth has been marked by the succession of large glacial–interglacial changes which shaped the relief of the Earth and eventually led toward modern biodiversity. Oceanic sedimentary sequences provide the most continuous records of these dramatic variations. Among the oceanic indicators of past climatic changes, the oxygen isotope composition of Foraminifera in deep-sea cores, as a proxy of past changes in global ice cap volume, has been one of the most insightful tool to reveal the history of the continental ice sheets. The most striking result of paleoceanographic studies using $\delta^{18}\text{O}$ was the discovery of periodic glacial–interglacial successions, which were paced by orbital forcing as theorized by Milankovitch's theory. While the late Pleistocene spectrum is mainly marked by the ~ 100 ka period, the succession of glacial and interglacial periods during the early Pleistocene period – from 2.6 to about 0.8 Ma – was marked by a very regular pacing of 41 ka. Moreover, oxygen isotope records showed that within the same interval, the buildup of ice caps in the high latitudes during glaciations was considerably smaller during the early Pleistocene than later. Finally, the configuration of the continents during the early Pleistocene was not significantly different than during the late Pleistocene. The 41 ka 'world' – the early Pleistocene – is thus a key period of the Earth's history when global climate changed toward modern climate without any strong external forcing changes. This period offers unique opportunities to infer processes at play in glacial to interglacial transitions.

Stratigraphy of the Early Pleistocene

In the oceanic realm, the combination of orbital cyclostratigraphy with paleomagnetism, biostratigraphy, and absolute

dating made possible the development of an extremely accurate and precise stratigraphy of early Pleistocene paleoceanographic records ([Figure 1](#)). The early Pleistocene encompasses the Gelasian, Calabrian, and Tyrhenian subdivisions. Recent changes in the stratigraphy have put the Pliocene–Pleistocene boundary at about 2.6 Ma, during marine isotope stage (MIS) 103 ([Rio et al., 1998](#)), also corresponding with the lower boundary of the Quaternary.

Pliocene–Pleistocene Boundary

The Global Stratotype Section and Point (GSSP) for the Pliocene–Pleistocene boundary was proposed in 1998 for the Gelasian stage, and placed close to the Gauss–Matuyama boundary (2.588 Ma; [Rio et al., 1998](#)). The GSSP is at Monte San Nicola, Sicily. In oceanic stable oxygen isotope records, the Pliocene–Pleistocene boundary is associated with MIS 103, corresponding to the onset of Northern Hemisphere glaciations as reflected in proxy records which are discussed later (ice-rafted debris (IRD), sea-surface temperatures (SSTs), loess records).

Early/Late Pleistocene Boundary and the Mid-Pleistocene Transition

While the beginning of the early Pleistocene is clearly defined, the end of the early Pleistocene period is informal. Conventionally, the Brunhes–Matuyama reversal (0.78 Ma) defines the early to mid-Pleistocene boundary ([Gradstein et al., 2005](#)). In paleoceanographic records, the period that leads to the dominance of the large 100 ka glaciations is called the mid-Pleistocene transition or mid-Pleistocene revolution. Because no formal definition was ever voted, and because it corresponds to a change in both time and frequency domain that depends upon the paleoceanographic record used, the age of this

boundary can vary from about 1 to about 0.65 Ma. Advanced time series statistical analyses using benthic $\delta^{18}\text{O}$ records as a proxy of past global changes in ice volume indicate that the midpoint of the transition in mean ice volume was 922 ± 12 ka, whereas the maximum amplitude in the 100 ka band was attained at 641 ± 9 ka (Mudelsee and Schulz, 1997).

Ice-Volume and Sea-Level Changes

During the early Pleistocene, a secular trend led to the onset of the large glaciations of the late Pleistocene. In the oceanic realm, this secular trend has been clearly recorded by deep-sea benthic Foraminifera $\delta^{18}\text{O}$ reconstructions, which are influenced by global ice-volume changes and by a minor contribution of deep-sea temperature changes, recently deconvolved using Mg/Ca paleothermometry. A number of records have been documented throughout the different oceanic basins that display early Pleistocene glacial–interglacial changes (Figure 2). Shackleton et al. (1976), using the historic V28-239 piston core from the equatorial Pacific ocean, were the first to reconstruct a complete record of $\delta^{18}\text{O}$ variations at a sampling rate that allowed the detection of glacial–interglacial cycles throughout the Pleistocene. Later, high-resolution records from the equatorial Atlantic (site DSDP 502) and from the Northern Atlantic (site DSDP 607) confirmed that the glacial–interglacial amplitude of $\delta^{18}\text{O}$ changes was reduced during the early Pleistocene (Prell et al., 1982; Ruddiman et al., 1989). More recently, at the same site, Sosdian and Rosenthal reconstructed the first long-term record of glacial–interglacial deep-sea temperature and ice-volume changes (Sosdian and Rosenthal, 2009). Three salient features characterize the early Pleistocene: (1) the global ice-volume difference between glacial and interglacial stages was reduced during the early Pleistocene; (2) the glacial–interglacial cycles were paced by a 41 ka rhythm during the early Pleistocene, whereas the late Pleistocene is marked by the onset of ~ 100 ka glacial–interglacial cycles; (3) global ice-volume buildup during glacial inceptions and ice-volume melting during terminations (deglaciations) are fairly symmetric during the early Pleistocene.

Amplitude of Ice-Volume Changes

The early Pleistocene was characterized by smaller glacial ice caps during glacial intervals, but also by ‘somewhat’ more ice during the interglacials (Prell et al., 1982). Accurate estimates of glacial and interglacial ice volumes during the early Pleistocene are still poorly constrained because of uncertainties in proxy-based methods. Two approaches have been followed to unravel deep-sea temperature effects from ice-volume changes on the benthic isotopic record. The first approach uses benthic paleothermometry (Sosdian and Rosenthal, 2009), and the second uses ice-sheet modeling to constrain the ice-volume component (Bintanja et al., 2005). Overall, using the former approach, temperature uncertainties and $\delta^{18}\text{O}$ -associated uncertainties induce a ± 32 m uncertainty in reconstructed sea levels during glacial–interglacial transitions (Figure 3). The amplitude of glacial–interglacial sea-level changes is reduced, compared to late Pleistocene oscillations, by approximately 20 m.

Pacing of Ice-Volume Changes

The main cyclicity of glacial–interglacial successions during the early Pleistocene has been shown to be close to obliquity (41 ka), in contrast to precession during the late Pliocene. This period is clearly detected in deep-sea benthic $\delta^{18}\text{O}$ records from all around the world (Lisiecki and Raymo, 2005), but also in planktonic records from the major ocean basins. Moreover, this 41 ka rhythm is a robust feature, because it can be detected in records whose timescales are based on independent stratigraphy (i.e., not based on Milankovitch cycles), as demonstrated in the landmark DSDP 607 record from the North Atlantic (Raymo and Nisancioglu, 2003; Ruddiman et al., 1989) and from the world’s oceans (Huybers and Wunsch, 2004). Lastly, this North Atlantic record clearly showed a co-variation of the $\delta^{18}\text{O}$ signal with IRD records, confirming that the melting of the large Northern ice caps was synchronous with the isotopic record.

Symmetry of Glacial and Interglacial Transitions

The last feature of ice-volume changes during the early Pleistocene is that the curve representing the succession of glacial and interglacial stages recorded in benthic $\delta^{18}\text{O}$ records following the 41 ka cycle described earlier is marked by a distinctive sinusoidal shape. This pattern clearly contrasts with the 100 ka sawtooth shape in the curve representing late Pleistocene ice-volume changes (Imbrie et al., 1993). The symmetry of early Pleistocene 41 ka glacial–interglacial changes implies a linear response of the climate system to orbital obliquity forcing, in contrast with late Pleistocene Ice Ages that suggest a strong nonlinear response of the climate system to orbital forcing. As discussed, the importance of total summer insolation, forced mainly by obliquity changes, may explain the nonskewed shape of glacial–interglacial changes.

Paleotemperature Changes

Since the early 2000s, the quantification of the oceanic temperature changes across glacial–interglacial cycles during the early Pleistocene has considerably improved. This progress is mainly due to the advance of geochemical proxies, such as alkenone paleothermometry and Mg/Ca in planktonic Foraminifera shells. Indeed, classical micropaleontological markers are affected by increased uncertainties with regard to the relevance of analogs as one gets further back into the past. Geochemical paleothermometers are less sensitive to this issue, though two issues may be critical for estimates of past temperature changes. First, preservation issues are critical for Mg/Ca paleothermometry, and floristic changes throughout the Pleistocene may change the specific phytoplankton biosynthesizing alkenones. A number of records have now been developed throughout the world’s oceans that shed light on both the long-term trends and glacial–interglacial changes in ocean-surface temperature during the early Pleistocene (Figure 3).

Long-Term Trend of Paleotemperature Changes

During the early Pleistocene and toward the mid-Pleistocene transition, a long-term cooling has been shown to affect both

Figure 3 Comparison of Pleistocene atmospheric pCO_2 concentrations measured in ice-core records (purple line; Lüthi et al., 2008) and inferred from boron isotope measurements in Foraminifera (Hönisch et al., 2009); western equatorial Pacific compilation of Mg/Ca-derived sea-surface temperatures (SSTs) (de Garidel-Thoron et al., 2005; Medina-Elizalde and Lea, 2005; Wara et al., 2005); eastern equatorial Pacific SSTs (Liu et al., 2008); sea-level changes inferred from benthic Foraminifera paleotemperature, deep-sea temperature changes (Sodrian and Rosenthal, 2009), and a benthic $\delta^{18}O$ stack (Lisiecki and Raymo, 2005).

the high latitudes and deep-sea waters. This cooling is a continuation of the long-term Pliocene trend that finally led to Pleistocene glaciations. The long-term cooling of deep-sea waters, first inferred from $\delta^{18}\text{O}$ in benthic Foraminifera, was confirmed by Mg/Ca paleothermometry on the same organisms at low resolution and has been further resolved more recently. This cooling also affected polar SSTs, as demonstrated by North Atlantic ocean $\delta^{18}\text{O}$ reconstructions of surface-dwelling Foraminifera. The high-latitude cooling is indirectly confirmed by low-latitude SST records from upwelling areas. Indeed, records of SSTs from the Benguela current and eastern equatorial Pacific showed that the long-term cooling observed in the high latitudes was also present at low latitudes. However, this pattern of cooling was restricted to the upwelling area (Marlow et al., 2000). Indeed, most of the subtropical surface ocean did not show any long-term cooling or warming throughout the Pleistocene (de Garidel-Thoron et al., 2005). Such a stability of Pleistocene subtropical temperatures has been observed in the western equatorial Pacific, in the western equatorial Atlantic (Sepulcre et al., 2011), and in the eastern equatorial Atlantic (de Garidel-Thoron et al., 2005; McClymont et al., 2005; Schefuß et al., 2004). The long-term cooling of high latitudes and upwelling SSTs, compared to the stability of subtropical SSTs, suggests an increase of meridional and zonal thermal gradients across the different oceans. This finding confirms the robustness of the alkenone and Mg/Ca methods, as their independent estimates of past SSTs converge toward the same results. In summary, while the subtropical ocean remained warm throughout the early Pleistocene, high latitudes and deep waters experienced a significant cooling during the early Pleistocene.

Glacial–Interglacial Changes

While there is a clear decoupling of subtropical SSTs with high latitudes and upwelling SSTs on the long-term trend, such a difference does not exist at the orbital timescale. During the 41 ka glacial–interglacials, both low- and high-latitude SSTs seem to have responded in phase to the obliquity forcing. During a maximum in obliquity, ice volumes were reduced, and SSTs at different latitudes around the world reached their maximum. Maximum SSTs at low latitudes in records from the eastern and western equatorial Pacific are thus out of phase with local insolation forcing (de Garidel-Thoron et al., 2005; Liu and Herbert, 2004). Moreover, the strong 41 ka signal in low-latitude SST records implies a remote forcing in the low latitudes by some high-latitude processes. The weakness of a strong precessional signal in low-latitude SST records further underlines the role of high-latitude insolation forcing on low-latitude climate response. Among the processes suggested to be at play for the phasing of low-latitude SST signals, low- to high-latitude insolation gradients have been suggested as a potential driver of early Pleistocene climate (Raymo and Nisancioglu, 2003). It was recently proposed that total insolation over the duration of summer in both Northern and Southern Hemispheres was the most likely driver of 41 ka glacial oscillations, rather than insolation changes in the Northern Hemisphere or latitudinal insolation gradients (Huybers, 2006).

Thermohaline Circulation Changes

Early Pleistocene global topography and bathymetry were not significantly different from those of the modern Earth. No major tectonic change can be invoked to explain the main Pleistocene paleoceanographic changes. The Panama Strait was closed at least 1 Ma prior to the Pliocene–Pleistocene boundary, and the configuration of straits in the Indonesian archipelago was likewise close to the modern one.

Thermohaline circulation has been clearly shown to dramatically change over the last climatic cycle (late Pleistocene). During an interglacial period such as the Holocene, the ‘conveyor’ is stronger than during glacial periods when thermohaline circulation is reduced. At the millennial timescale, there is a large body of evidence demonstrating that thermohaline circulation was weaker during stadials of the last glacial stage and during millennial cold snaps, at least in the North Atlantic region. Early Pleistocene thermohaline circulation changes have been extensively investigated in order to test whether similar changes in oceanic circulation occurred in the distant past.

The main evidence used to reconstruct past changes in thermohaline circulation is provided by the $\delta^{13}\text{C}$ composition of benthic Foraminifera from North Atlantic deep-sea cores at different depths over the water column. Past $\delta^{13}\text{C}$ gradients are traditionally used as a tracer of the different water masses, and give insights on past changes in North Atlantic Deep Water production. However, $\delta^{13}\text{C}$ in deep waters from the North Atlantic is also influenced by the production rate of deep water in the Southern Ocean. During the early Pleistocene, few changes were observed in the modes of variability of North Atlantic deep waters. However, at the end of the early Pleistocene, deep sites from the North Atlantic record a mid-Pleistocene reduction in glacial $\delta^{13}\text{C}$ (Raymo et al., 1997). Observations on the relative influence of northern and southern ocean deep waters led to the formulation of two different hypotheses: (1) this observation was first interpreted in the early 1990s to be indicative of enhanced glacial suppression of the North Atlantic Deep Water at the end of the early Pleistocene (Raymo et al., 1990); (2) however, recent studies point toward a more critical role of the production rate of deep waters around Antarctica on the isotopic composition of deep-sea waters in deepest sites from the Northern Atlantic (Raymo et al., 2004). This increased role of the Southern ocean in deep-water masses would imply slighter variations in thermohaline circulation during the mid-Pleistocene. In summary, though thermohaline circulation likely changed over the course of the early Pleistocene, there is as yet no clear evidence of the amplitude of these changes and of their role on global climate.

From 41 to 100 ka: The Mid-Pleistocene Transition

The period that marks the onset of the largest glaciations of the Cenozoic era, at the end of the early Pleistocene, is called mid-Pleistocene transition or mid-Pleistocene revolution. During this transition, the climate system bifurcated from a linear response to obliquity forcing to a nonlinear response to orbital forcing, which is characterized by a strong 100 ka period, presumably correlated with orbital eccentricity. Note that a

recent study indicates that the statistical significance of late Pleistocene 100 ka cycles is weak, and that deglaciations (terminations) occurred each two or three obliquity cycles (41 ka; Huybers and Wunsch, 2005). In any case, the period preceding the mid-Pleistocene revolution led to the largest Pleistocene ice caps, and a shift from a linear (early Pleistocene; Imbrie et al., 1992) to a nonlinear climate response (late Pleistocene; Imbrie et al., 1993). The Mid-Pleistocene transition is not associated with any abrupt changes in orbital forcing. Many hypotheses have been formulated to account for this. All these hypotheses suggest a mechanism that preserves Northern Hemisphere ice sheets throughout one or two obliquity cycles, therefore allowing the buildup of large late Pleistocene ice sheets.

Thermohaline Switch

In this hypothesis, marine feedback triggered a marine-induced instability of continental ice volume at the mid-Pleistocene transition. This feedback was attributed to the reorganization of the 'global conveyor belt' of thermohaline circulation (DeBlonde and Peltier, 1991). It was also suggested that the critical increase in Northern ice volume modified Arctic oceanic circulation, and therefore altered global patterns of ocean circulation (Berger et al., 1994). As discussed earlier (see section 'Thermohaline Circulation Changes'), changes in early Pleistocene thermohaline circulation are still poorly resolved and cannot be used to assess this hypothesis.

Atmospheric CO₂ Hypothesis

The long-term cooling trend that affected the high latitudes might have been caused by a secular decrease of atmospheric CO₂ concentration. In this hypothesis, during the early Pleistocene, higher concentrations in atmospheric CO₂ prevented the conservation of Northern Hemisphere ice sheets over two precession cycles. This hypothesis has been successfully simulated (Berger et al., 1999), but direct evidence for the secular decrease in atmospheric CO₂, likely from tectonic processes, has not been noted in ice-core records (Lüthi et al., 2008) or in recent boron isotope reconstructions of atmospheric CO₂ (Figure 3; Hönlisch et al., 2009).

Sea-Ice Switch Hypothesis

This hypothesis is based on deep-water cooling during the Pleistocene, inferred from benthic Foraminifera records (see section 'Ice-Volume and Sea-Level Changes'). In this hypothesis, the long-term cooling of the deep ocean resulted in an extensive sea-ice cover of the polar oceans. Such an extensive sea-ice cover activated the 'sea-ice switch' that changed the ablation and accumulation rates over the continental ice sheets (Tziperman and Gildor, 2003). This mechanism reproduces a change from a linear to a nonlinear response of the climate system. However, this hypothesis has not yet been validated by any proxy data of sea-ice cover.

Regolith Hypothesis

In this hypothesis, the weathered soil (regolith) lying beneath the Laurentide ice sheet was progressively eroded during the

Pliocene and early Pleistocene glacial cycles. This soft bed could sustain only thin ice sheets which responded linearly to orbital forcing (precession and obliquity). By the mid-Pleistocene, mineralogical and geochemical data indicate that the regolith was largely eroded, allowing the ice sheet to rest directly on the crystalline bedrock and enabling the ice sheets to reach greater heights (Clark and Pollard, 1998).

Chaotic Response to Obliquity Forcing

This hypothesis posits that the switch from the 41 to 100 ka results from the chaotic nature of glacial Pleistocene cycles, and that the change in frequencies might occur spontaneously (Huybers, 2009). In this hypothesis, the late Pleistocene 100 ka cycles are, in fact, close to multiples of obliquity cycles (mostly 80 ka), and no large change in external forcing occurred during this time interval. This hypothesis was tested using a modified version of the Imbrie and Imbrie ice-volume model forced by obliquity.

Walker Circulation Hypothesis

Preceding the mid-Pleistocene transition (starting about 1 Ma ago), the difference between western and eastern equatorial Pacific SSTs increased, enhancing the zonal meridional Walker circulation (see section 'Paleotemperature Changes'), following the long trend initiated in the late Pliocene (Wara et al., 2005). The increase in the Walker circulation was synchronous with a long-term freshening of the western equatorial Pacific. Such a pattern, which nowadays occurs during the La Niña phase of the El Niño Southern Oscillation, is correlated with enhanced freshwater fluxes toward the high latitudes, and also to a likely decrease of the poleward heat flux, based on the global energy balance (Philander and Fedorov, 2003). In this hypothesis, increased accumulation of continental ice was thus induced by low-latitude climate changes which altered poleward freshwater and heat fluxes (de Garidel-Thoron et al., 2005; McClymont and Rosell-Melé, 2005). This hypothesis posits that permanent El Niño conditions, such as in the late Pliocene–early Pleistocene, would inhibit the growth of large ice sheets over North America (review by Chiang, 2009). In line with this hypothesis, Huybers and Molnar (2007) inferred that the effect of warmer eastern Pacific surface waters would exceed the effect of obliquity forcing on the ablation rate of North Hemisphere ice sheets, based on modern observations. Therefore, the establishment of the zonal temperature gradient in the equatorial Pacific during the mid-Pleistocene might have favored the onset of large late Pleistocene glaciations.

Millennial-Scale Dynamics in the Early Pleistocene?

Abrupt climatic changes in the late Pleistocene have been extensively described from global oceanic sedimentary records. In the millennial band, Dansgaard–Oeschger events and Heinrich events paced MIS 3. Though these events were first characterized from sites in the North Atlantic, these abrupt changes have been shown to have remote effects on climate. These events, characterized by massive iceberg discharges in the North Atlantic ocean, correlated with significant sea-surface

cooling at relatively low latitudes, and were eventually linked to changes in global thermohaline circulation. In the early Pleistocene, very few sedimentary records have been studied at millennial resolution (Mc Intyre et al., 2001; Raymo et al., 1998). Among the few existing studies, Raymo et al. (1998) have shown that during the early Pleistocene (MIS 40 and 44), IRD, indicative of iceberg discharges, were present in deep-sea sediments from the North Atlantic and were found to exhibit a clear millennial signal (site ODP983). Though surface Foraminifera fauna did not show a similar pattern of millennial changes, these IRD indicate that 'Dansgaard-Oeschger-like' events occurred during the early Pleistocene glacials when the ice sheets were reduced, compared to the last climatic cycle. Deep-sea sediment records cannot yet characterize the patterns and phasing of global climate changes associated with these millennial events, but there is robust evidence for millennial-scale climate change during early Pleistocene Ice Ages. The origin of millennial-scale oscillations during the early Pleistocene cannot yet be ascribed to any particular process, though it is likely that the same processes at play during the late Pleistocene should also have been critical to abrupt changes in the 41 ka world.

Conclusions

The early Pleistocene offers a unique perspective on how the global climate system evolved from a warmer mode relative to the preindustrial mean state. Paleoclimatographic records from all around the world clearly indicate that the climate system responded linearly to orbital obliquity (41 ka) and precessional (21 ka) forcing during the early Pleistocene, and changed during the mid-Pleistocene to become dominated by 100 ka cycles. However, the exact processes leading to the transmission of the obliquity signal to the global climate (and in particular to the low latitudes) and the evolution of the dominant periodicities remain uncertain. The role of thermohaline circulation in early Pleistocene glacial-interglacial cycles does not seem to be preponderant, though the available data cannot precisely constrain its past changes. Finally, the processes leading to the onset of the largest glaciations of the Cenozoic, after the mid-Pleistocene transition, took place after a long-term cooling of the high latitudes, contrasting with a low-latitude stability in SSTs, and of an increase in the meridional Walker circulation.

Late Pleistocene North Atlantic

D M Anderson, University of Colorado, Boulder, CO, USA; NOAA National Climatic Data Center, Boulder, CO, USA

Modern Surface and Deep Circulation of the North Atlantic

The modern circulation of the North Atlantic can be divided into the wind-driven circulation in the upper few 100 m and the meridional overturning circulation that moves water masses formed at the surface through the abyss. Meridional overturning is driven by a combination of buoyancy and dynamic forcing, including processes operating in the Southern Ocean, and exciting research today in oceanography and paleoceanography concerns the processes that control the overturning circulation and thus influence climate on a broad scale.

Surface Circulation

The westerly winds blowing across the North Atlantic at mid-latitudes and the easterly trade winds at lower latitudes drive a clockwise gyre circulation in the North Atlantic (**Figure 1**). The Gulf Stream flows rapidly northward along the eastern coast of North America and northeastward across the North Atlantic, the Canary Current flows slowly southward along the west coast of Africa, and an equatorial current flows westward along the equator. One branch of the surface circulation continues northward in the Labrador, Greenland, and Iceland Seas, and even farther north into the Arctic. Cold Arctic water flows southward along the east coast of Greenland, around the southern tip of Greenland, and forms a small gyre in the Labrador Sea (not shown).

Deep Circulation and the Meridional Overturning Circulation

Several processes, including heat loss to the atmosphere and mixing with cold Arctic water, increase the density of surface waters in the region of the Greenland, Iceland, and Norwegian Seas (the Nordic Seas) and in the Labrador Sea, so that the surface waters convect (sink), forming the North Atlantic Deepwater (NADW) that flows southward along the western boundary between 2000 and 4000 m in the North Atlantic (**Figure 1**, blue arrows). The deep branch of the meridional overturning circulation is much slower than the surface circulation, making a circuit over centuries rather than decades, and the current speeds are not easily directly measured. The deep circulation can be traced from conservative physical properties such as temperature and salinity that are acquired at the surface and subsequently changed only by mixing with other water masses (**Figure 2**). NADW forms in the Nordic and Labrador Seas and flows southward into the South Atlantic, observed as a maximum in salinity (**Figure 2**). In the South Atlantic, the Antarctic Intermediate Water, identified by low salinity, flows northward above NADW. Antarctic Bottom Water originates near Antarctica and flows northward across the equator in the deep Atlantic below NADW. The combination of intermediate salinity combined with very low temperature makes Antarctic Bottom Water the most dense water mass in this simplified view of the deep circulation.

The conveyor belt is another term given to the combined surface and deep circulation that carries surface water northward in the Gulf Stream, where it sinks in the Nordic Seas and flows out of the North Atlantic and into the other ocean basins. The surface return flow to the North Atlantic is principally from the Pacific via the Indian Ocean. The conveyor analogy describes the ideas that the circulation forms a complete loop, and that the motion transports heat, salt, and nutrients throughout the ocean basins. Model-based studies indicate that the strength of the overturning circulation depends partly upon surface water in the Nordic Seas being dense enough to convect. This requirement adds a nonlinear, threshold process to the Atlantic circulation. If ice sheet melting or precipitation or runoff were to freshen the Nordic Seas so that surface waters became too buoyant, the overturning circulation might be reduced or stop completely, abruptly when the threshold is crossed. Conversely, when the surface waters become dense enough to sink, the overturning circulation might resume abruptly. The late Pleistocene paleoceanographic records discussed later provide concrete evidence for on/off behavior of the thermohaline circulation during the late Pleistocene.

Wind-driven and deep circulations are not independent. The Gulf Stream can be considered the upper limb of the overturning circulation and is dynamically driven by the surface wind field. The atmospheric circulation influences not only the winds that drive the surface circulation but also the deep ocean circulation by creating salty, dense waters through excess evaporation in the subtropical region, by producing cold, freshwater in the Arctic region through excess precipitation and runoff, and heat loss, and by creating a region of high seasonality and deep winter mixing beneath the westerly winds in the North Atlantic.

Evolution During The Pleistocene

The stacked benthic $\delta^{18}\text{O}$ composited from 57 sites reflects a combination of ice volume change and deep ocean temperature change, and reveals a gradual evolution throughout the Pleistocene (Lisiecki and Raymo, 2005; **Figure 3**). The average temperature of the Earth cooled, likely dominated by cooling at high latitudes with little change at low latitudes. The volume of the ice sheets increased. A steplike increase in the concentration of ice-rafted debris (IRD) signaled the expansion of large-scale Northern Hemisphere ice sheets 2.74 Ma (**Figure 3**; Jansen et al., 2000). Expansion of the Northern Hemisphere ice sheets around 2.7 Ma has also been interpreted from an increase in the concentration of long-chain n-alkanes in North Atlantic sediments (Naafs et al., 2012). The development of glacial outwash plains would be expected to increase the supply of aeolian sediment to the North Atlantic, including n-alkanes derived from higher plant waxes (Naafs et al., 2012). Sea surface temperature (SST) in the North Atlantic (Site 607, 41°N) cooled throughout the Pleistocene, with two steps

occurring in the late Pliocene (3.1–2.4 Ma) and the mid-Pleistocene transition (1.5–0.8 Ma; Lawrence et al., 2010). The most remarkable aspect of this evolution was that it occurred in the absence of a change in orbital forcing, implicating a fundamental change internal to the climate system (Clark et al., 2006). Many hypotheses for the origin of this evolution focus on the mid-Pleistocene transition, when the variance in the benthic oxygen isotope record shifted from a dominantly 41 000-year period to a dominantly 100 000-year period. Why ice volume varies at the 100 000-year period when

there is so little variation in insolation at this periodicity has been termed the 100-ka cycle problem, and the unexpectedly small variance in the precessional band (23 000 years) prior to the transition has been attributed to a shift in the relative proportions of ice volume in the Northern and Southern Hemispheres (Raymo et al., 2006).

Mid-Pleistocene Transition

Many aspects of the climate changed across the mid-Pleistocene transition between 1.25 and 0.7 Ma (Clark et al., 2006). The average $\delta^{18}\text{O}$ increased, indicating deep ocean cooling and greater ice volume, the variance increased (Figure 3), and the dominant period of variation shifted from the 41 000-year obliquity cycle to the 100 000-year period. The increase in variance is attributed to a combination of deep ocean cooling and increase in ice volume; the North Atlantic sea surface also cooled (Figure 3). Upwelling increased in tropical ocean regions and African and Asian monsoon intensity and aridity increased, summarized by Clark et al., 2006. Changes in the meridional overturning are difficult to reconstruct. Vertical and between-ocean gradients in benthic foraminifer $\delta^{13}\text{C}$ from an array of sites suggest that the coupling between overturning and glaciation has changed through time and across the mid-Pleistocene transition; however, the multiple influences on $\delta^{13}\text{C}$ complicate this interpretation.

Glacial–Interglacial Cycles

The glacial–interglacial cycles of the late Pleistocene North Atlantic are one of the best-studied aspects of the Pleistocene. SSTs have been reconstructed from many different proxies, and surface and deep circulations inferred from tracers such as $\delta^{13}\text{C}$. The following discussion focuses on the changes that occurred during the Last Glacial Maximum (LGM), recognizing that previous glacial stages share many of the same characteristics at least for the last five glacial cycles.

Figure 1 Simplified view of the North Atlantic circulation shows warm water flowing clockwise around the North Atlantic gyre (red loop), with a branch flowing northward to the Labrador and Greenland/Iceland Seas (red arrows), where it cools, sinks, and flows southward along the western boundary of the deep Atlantic (blue arrows). Reproduced from Holloway G and Proshutinsky A (2007) Role of tides in arctic ocean/ice climate. *Journal of Geophysical Research* 112: C04S06.

Figure 2 Salinity (psu) as a function of depth and latitude in the Atlantic. The principal water masses can be identified and traced back to their origin at the high-latitude sea surface by their characteristic salinity and temperature characteristics. Reproduced from Conkright ME, Locarnini RA, Garcia HE, et al. (2002) *World Ocean Atlas 2001: Objective Analyses, Data Statistics, and Figures, CD-ROM Documentation*. Silver Spring, MD: National Oceanographic Data Center; from the World Ocean Atlas.

Figure 3 North Atlantic ice-rafted debris (IRD) (Jansen et al., 2000), sea-surface temperature (SST) (Site 607; Lawrence et al., 2010), and the global benthic oxygen isotope stacked record (Lisiecki and Raymo, 2005). Ice sheet expansion refers to expansion of large-scale Northern Hemisphere ice sheets identified on the basis of IRD, and the mid-Pleistocene transition refers to the period of increasing variance in $\delta^{18}\text{O}$, culminating in the dominance of the 100 000-year cycle after 700 000 years BP.

Climate Sensitivity of the North Atlantic

The most dramatic aspect of the glacial Atlantic is the large difference in SST with respect to the present. Whether one examines the pioneering maps created by Climate: Long-Range Investigation, Mapping, and Prediction (CLIMAP; CLIMAP Project Members, 1981) or the Glacial Atlantic Ocean Mapping (GLAMAP; Pflaumann et al., 2003), or Multiproxy Approach for the Reconstruction of the Glacial Ocean surface (MARGO) compilation (Waelbroeck et al., 2009), one observes that the middle-to-high latitudes cooled more than lower latitudes, and also that the North Atlantic sea surface cooled much more than other oceans at similar latitudes (Figure 4). According to the CLIMAP and GLAMAP reconstructions, the region between 45° and 60° N cooled by more than 10 °C (Figure 4). North of 60° N, the difference from today is not as large because seawater cannot cool below about −1.5 °C before sea ice forms. Here sea ice extended farther south. In contrast, mid-latitudes in other ocean basins cooled by only a few degrees. In the subtropical gyres in all oceans, the sea

surface cooling was smallest, and in the CLIMAP reconstruction, several of the gyres were warmer than today. Along the equator in the Atlantic, the cooling was small but larger than in the subtropics. Cooling along the equator was most pronounced at the eastern margin, and has been attributed to stronger coastal and equatorial upwelling driven by stronger trade winds (Waelbroeck et al., 2009).

Today, the sea ice margin migrates seasonally in the high North Atlantic, extending in winter across the Nordic Seas north of Fram Strait (80° N) and southward along the east coast of Greenland, and retreating northward each summer. During glacial times as the sea surface cooled, the southern sea ice margin moved toward the equator. The southern extent of sea ice and its seasonal cycle has always been poorly constrained, its boundary often inferred only from reduced sediment accumulation. Early CLIMAP reconstructions positioned the summer and winter sea ice margin far south of its present latitude, with perennial sea ice cover across the Nordic Seas. Later reconstructions (Pflaumann et al., 2003) based on foraminifer faunal temperature reconstructions have indicated that

Figure 4 Change in zonal average sea surface temperature between glacial and present (negative indicates glacial was cooler than today). North Atlantic from CLIMAP (black line), North Atlantic from GLAMAP (black dashed), North Indian-Pacific from CLIMAP (red), South Atlantic (blue), South Indian-Pacific (green) (Pflaumann, 1985; CLIMAP Project Members, 1981; Pflaumann et al., 2003).

the winter sea ice margin was not so extensive, with an ice-free channel extending in winter as far north as 50° or 60°, and that the summer sea ice margin was much less extensive than originally determined, extending across the Arctic and Fram Strait. The revised summer sea ice margin is not much different than today, and leaves the Nordic Seas ice-free during glacial summers. Until unambiguous indicators of sea ice for each season are found, reconstructing the sea ice margin will remain an active area of research, highly significant in understanding possible sites of deepwater formation during glacial times, the albedo of the northern North Atlantic, and the receipt of solar radiation and the exchange of heat between ocean and atmosphere.

Meridional Overturning

Changes in the production of NADW, and the vertical gradients in water mass properties have been inferred from many proxies, including $\delta^{13}\text{C}$, Cd/Ca , $^{231}\text{Pa}/^{230}\text{Th}$, and $^{143}\text{Nd}/^{144}\text{Nd}$. NADW is depleted in nutrients (high $\delta^{13}\text{C}$ and low Cd/Ca) and can be distinguished from Antarctic bottom water (low $\delta^{13}\text{C}$ and high Cd/Ca). One of the most well-documented discoveries in the North Atlantic is the change in $\delta^{13}\text{C}$ between modern and glacial times (Figure 5), inferred to represent a decrease in NADW production during glacial times, and its replacement by a water mass that formed farther south and descended to a shallower depth (Glacial North Atlantic Intermediate Water; Lynch-Stieglitz et al., 2007). Results based on Cd/Ca are consistent with the section developed from $\delta^{13}\text{C}$ (Figure 5, bottom panel). One additional approach, based on U-series decay products (^{231}Pa and ^{230}Th), provides the only measure of the rate of circulation. The export of ^{231}Pa relative to ^{230}Th indicates no significant difference at the LGM relative to the present (Yu et al., 1996); however, abrupt changes during the deglaciation are indicated at some sites (McManus et al., 2004; see Section 'The Last Deglaciation').

One of the critical questions has been the extent to which NADW production drives, or responds to, glacial-interglacial climate change in the North Atlantic region. Studying different proxies found in South Atlantic cores, Piotrowski et al. (2005)

show that changes in benthic foraminifer $\delta^{13}\text{C}$ and changes in ϵ_{Nd} , both reflecting NADW formation, followed the ice growth (inferred from benthic $\delta^{18}\text{O}$) during the transition from the last interglacial interval (marine isotope stage (MIS) 5a) to the next glacial interval (MIS 4), decreasing NADW production, and later followed the initial warming (inferred from Greenland and Antarctic ice cores) at the end of the last glaciation (MIS 2), increasing NADW production). The results are consistent with the hypothesis that NADW production changes are an amplifier, but not an initial trigger, of the late Pleistocene Ice Ages.

Millennial-Scale Variability

Millennial-scale variability is discussed in detail in a separate article, and its inclusion here seeks to highlight North Atlantic paleoceanographic records and their significance. Any discussion of marine records of millennial-scale variability must include the caveat that millennial-scale events are not often preserved in marine sediments. Deep-sea sedimentation rates are typically 1–5 cm ka^{-1} , and bioturbation (mixing of sediment by benthic organisms at the seafloor) can homogenize sediment across 10 cm, attenuating the amplitude, and sometimes completely erasing events of 1000-year (1–3 cm) duration. The discovery of millennial-scale events in ice cores motivated a vigorous effort to find and analyze higher sedimentation rate (>10 or >20 cm ka^{-1}), or minimally bioturbated cores. Since then, millennial-scale variability has been reported in cores from the North Atlantic, and sites as far away as the Cariaco Basin, the California Margin, the Arabian Sea, and the South China Sea. The magnitude of SST change is greatest in the North Atlantic, consistent with the amplitude of glacial-interglacial change. While the following discussion examines the millennial-scale variability during the last glacial, from 120,000 to 10,000 years BP (Figure 6), longer records show that millennial-scale variability was a persistent feature of at least the preceding four glacial intervals (the last 500,000 years), prevalent whenever benthic $\delta^{18}\text{O}$ exceeded 3.5 per mil (McManus et al., 1999). These oscillations and events are

Figure 5 (a) The modern distribution of dissolved phosphate ($\mu\text{mol l}^{-1}$) – a biological nutrient – in the western Atlantic (Conkright et al., 2002). Also indicated is the southward flow of NADW, which is compensated by the northward flow of warmer waters above 1 km, and the Antarctic Bottom Water (AABW) below. (b) The distribution of the carbon isotopic composition ($^{13}\text{C}/^{12}\text{C}$, expressed as $\delta^{13}\text{C}$, Vienna Pee Dee belemnite standard) of the shells of benthic Foraminifera in the western and central Atlantic during the LGM (Bickert and Mackensen, 2004; Curry and Oppo, 2005). Data from different longitudes are collapsed in the same meridional plane. (c) Estimates of the Cd (nmol kg^{-1}) concentration for LGM from the ratio of Cd/Ca in the shells of benthic Foraminifera (Marchitto and Broecker, 2006). Today, the isotopic composition of dissolved inorganic carbon and the concentration of dissolved Cd in seawater both show “nutrient”-type distributions similar to that of PO_4 .

absent or much reduced during the postglacial period. The absence of this variability during interglacial times, the abrupt, sawtooth character of the cycles, and the long time between events (thousands of years) have led to many explanations that involve the interaction between ice sheet growth and decay, sea

ice extent, and the surface and deep circulations in the North Atlantic.

Two different types of millennial-scale variability are observed during the last glacial cycle in the North Atlantic. Dansgaard–Oeschger events describe a series of warm (interstadial)

Figure 6 Millennial-scale variability in the North Atlantic during the late Pleistocene. (a) GISP2 oxygen isotope record with interstadial (warm) Dansgaard–Oeschger events labeled; (b) concentration of ice-rafted lithic fragments at Site 980 (H0–H6 are Heinrich layers); (c) percentages of *Neogloboquadrina pachyderma* left coiling in North Atlantic core; sediment reflectance in Cariaco Basin Site 1008. Data obtained from the World Data Center for Paleoclimatology <http://www.ncdc.noaa.gov/paleo/> from; Bond et al. (1993); Grootes and Stuiver (1997); McManus et al. (1999); Peterson et al. (2000).

and cool (stadial) events that are recorded in the oxygen isotopes of Greenland ice cores. Twenty-five events are numbered during the last glacial period, each lasting from 600 to 2000 years, and each is characterized by progressive cooling followed by abrupt warming (Figure 6(a)). At Site 980 in the North Atlantic, D–O events are evident as shifts in foraminifer abundance (Figure 6(c)), high ratios of *Neogloboquadrina pachyderma* left indicating cooler SSTs (Bond et al., 1993), and also in alkenone-based SST reconstructions of the Bermuda Rise at 35°N in the North Atlantic (Sachs and Lehman, 1999). Farther south in the Cariaco Basin, millennial-scale events appear in time series of gray scale in the Cariaco Basin (a proxy for plankton productivity and basin anoxia), indicating that at least the basin-scale surface circulation is involved.

Compared to the ice cores, the cycles found in the marine sediment records are not as pronounced; however, bioturbation complicates the effort to map the geographic extent of D–O variability throughout the Atlantic.

Heinrich events are other millennial-scale events that occurred during the last glacial period. Heinrich events were initially defined on the basis of coarse sediments found in discrete layers in North Atlantic sediments, and represent times when coarse ice-rafted material was transported farther south during massive iceberg discharge events from the Laurentide and other smaller ice sheets. Six events have been widely identified in North Atlantic sediments (H1, 14 300; H2, 21 000; H3, 27 000; H4, 35 500; H5, 52 000; and H6, 69 000 years BP), each occurring at the coldest part of a D–O cycle

Figure 7 Thickness (cm) of Heinrich layer 1 based on whole-core magnetic susceptibility; inset shows the thickness as a function of longitude. Reproduced from Dowdeswell JA, Maslin M, Andrews JA, and McCave IN (1995) Iceberg production, debris rafting, and the extent and thickness of Heinrich layers (H-1, H-2) in North Atlantic sediments. *Geology* 23: 301–304. <http://geology.gsapubs.org/>. © Geological Society of America.

(Figure 6). Most of the melting of icebergs occurs along the Polar Front, and the southern edge of the IRD belt therefore reveals that the Polar Front extended farther south during H events (Figure 7). Subsequent studies have also shown that the H events are characterized by colder SST in addition to extensive ice rafting, and by a freshwater anomaly farther north indicated by $\delta^{18}\text{O}$.

The H events are also characterized by changes in NADW production, in the sense that the cold stadial events were accompanied by reduced NADW production, possibly reduced production of Glacial North Atlantic Intermediate Water, and a relative increase in the proportion of Antarctic Bottom Water and Antarctic Intermediate Water at Atlantic sites. NADW production appears most reduced during H events. One sequence of events that emphasizes the instability of ice sheets in driving millennial-scale variability considers a gradual accumulation of ice over thousands of years, accompanied by decreased NADW production that further cools the North Atlantic toward the stadial state. Instability in the ice sheet eventually leads to abrupt, catastrophic release of ice into the North Atlantic, which freshens the North Atlantic upon melting and stops the production of NADW. Following ice sheet collapse, freshwater input to the North Atlantic is reduced, salinity increases again, and NADW production resumes, rapidly warming the North Atlantic. Problems exist even with this simplified sequence of events, and alternate models have been proposed that attempt to fit all the observations.

The Last Deglaciation

The sequence of events that occurred in the North Atlantic during the last deglaciation provides important clues regarding cause and effect, and the interaction between ice sheets,

atmosphere, and ocean circulation. Uncertainties in radiocarbon dating (± 100 years for marine sediments) continue to make correlation among records difficult, and even the strategy to analyze different proxies from a single core to determine leads and lags among proxies often has uncertainty (± 100 or more years). The timing and changing routes of meltwater discharge from the Arctic, and from the Laurentide and Eurasian Ice Sheets remain poorly constrained. Therefore, while the general sequence is becoming increasingly well known, significant uncertainty surrounds leads and lags and the timing of abrupt climate changes that occurred during the last deglaciation.

The oxygen isotope record from the GISP2, reflecting primarily the surface air temperature over Greenland, provides a useful framework to identify many of the events that occurred during the deglaciation (Figure 8). Readily apparent is the cooling that occurred during the LGM with respect to the Holocene, the initial warming during the Bølling/Allerød (B/A), the return to colder conditions during the Younger Dryas (YD), and the final warming that led to the postglacial North Atlantic climate (Holocene). The record of SST from the subpolar North Atlantic (core SU8118 off Portugal) follows a very similar history with respect to both the timing and amplitude of events (Figure 8(b)). The planktonic oxygen isotope record (Figure 8(c)) from the subtropical North Atlantic (GGC5, Bermuda Rise) reflects both the melting of the ice sheets, about 1.1 per mil, and a component related to warming of the sea surface (also about 1 per mil, equal to about 4 °C). Based on these records, during the deglaciation the subpolar North Atlantic warmed by 12 °C, and the subtropical North Atlantic warmed by about 4 °C, both increases interrupted by a cooling of a few degrees during the YD. The sedimentary $^{231}\text{Pa}/^{230}\text{Th}$ measured on the same core (GGC5) shows that NADW production was reduced compared to the Holocene at

Figure 8 Sequence of events during the last deglaciation in the North Atlantic. Reproduced from [McManus JF, Francois R, Gherardi J-M, Keigwin LD, and Brown-Leger S \(2004\)](#) Collapse and rapid resumption of Atlantic meridional circulation linked to deglacial climate changes. *Nature* 428: 834–837. Events labeled include the Last Glacial Maximum (LGM), Heinrich event 1 (H1), the Bølling/Allerød (B/A), the Younger Dryas (YD), and meltwater pulse 1A (MWP 1A). (a) GISP2 oxygen isotope record, (b) sea-surface temperature (SST) estimates from the subpolar North Atlantic based on planktonic foraminifer assemblages in core SU8118, (c) three-point running mean of planktonic $\delta^{18}\text{O}$ and sedimentary $^{231}\text{Pa}/^{230}\text{Th}$ from core GGC5 (decreases in this ratio indicate greater NADW production, and increases in the ratio indicated reduced NADW production; the ratio 0.093 indicates no differential removal of the isotopes by the deep circulation), and (d) sea level rise determined from Barbados corals.

the LGM, ceased toward the end of the LGM during H1 (reaching the production ratio of 0.093), increased during the B/A, and decreased during the YD before increasing toward Holocene values ([Figure 8\(c\)](#)). A peak in the concentration of IRD occurred in cores throughout the region during H1 ([Figure 7](#)), and other evidence has been compiled indicating that the sea surface cooled and freshened, changes that could have led to reduced NADW production as a result of ice melting ([Sarthein et al., 1992](#)). Reconstructing the melt history of individual ice

sheets remains difficult. The record of sea level determined from Barbados corals, integrating melting from all the ice sheets ([Figure 8\(d\)](#)) shows that sea level was lowest 18 000 years ago, and increased most rapidly during two intervals (meltwater pulse 1A (MWP-1A), [Figure 8\(d\)](#); and MWP-1B, not labeled). These meltwater pulses have been suggested as the cause of thermohaline circulation change during the deglaciation; however, this interpretation remains controversial, and difficult to evaluate because of dating uncertainty.

Based on the comparison between summer insolation at 65° N and the records of early ice melting in the Nordic Seas, a series of papers examined the role of the North Atlantic freshening in driving the deglaciation through changing NADW production. This hypothesis has been challenged by data from the tropics. By comparing the $\delta^{18}\text{O}$ signal in planktic foraminifers with the record of tropical SST based on Mg/Ca from the same samples, it is apparent that the increase in tropical SST leads the melting of the ice sheets (Visser et al., 2003). When the ice core record of atmospheric carbon dioxide is correlated to these records, tropical (and Antarctic) warming and atmospheric carbon dioxide increase are shown to be in phase, both occurring before the $\delta^{18}\text{O}$ depletion during the last deglaciation (Visser et al., 2003). Comparing proxies for NADW production based on $\delta^{13}\text{C}$ and ϵ_{Nd} , Piotrowski et al. (2005) show that the resumption of NADW during the deglaciation followed the warming observed in ice core records. Thus, while ice melt and NADW production may be linked, they appear to follow the warming in the tropics and the increase in carbon dioxide in the atmosphere. In this interpretation, ice sheet melting in the North Atlantic does not initiate the deglacial sequence; however, changes in NADW, sea ice, and land and ocean albedo may be powerful amplifiers that lead to the high sensitivity of climate in the North Atlantic.

Late Pleistocene South Atlantic

Introduction

The South Atlantic Ocean receives inflows from the Pacific, the Indian and the Southern Ocean and plays a significant role in the coupling of oceanic processes between these basins and the North Atlantic. An important feature of the present-day circulation in the South Atlantic is the cross-equatorial flow of warm upper layer waters into the North Atlantic, which are imported to compensate for the southward flow of North Atlantic Deep Water (NADW). The associated heat transport into the North Atlantic has a considerable effect on the modern climate (e.g., Wefer et al. (2004)). Processes in the South Atlantic can affect this heat transport and thus can have consequences for climates elsewhere.

The current systems in the South Atlantic are also critical for the nutrient budget of the ocean. The frontal region between the South Atlantic and the Southern Ocean is the ventilation area for South Atlantic central and intermediate water masses that spread northward into the Atlantic. Since these water masses are derived from nutrient-rich Antarctic surface waters, they are the main source of nutrients to sustain the productivity in the eastern boundary upwelling regions of the tropical and subtropical Atlantic.

The knowledge of past variations of the Atlantic circulation and how these variations led to changes in sea-surface temperature (SST), productivity, and atmospheric circulation are critical to our understanding of the role of the South Atlantic in long-term and abrupt climate change. In recent decades, these issues have been addressed by investigating late Pleistocene sediments in the South Atlantic.

Present-Day Circulation of the South Atlantic

The dominant circulation system of the South Atlantic Ocean is the anticyclonic Subtropical Gyre (Figure 1; see Stramma and England (1999) and Wefer et al. (1996) and references therein). The gyre is driven by the general atmospheric circulation, which is dominated by SE trade winds. The eastern part of the Subtropical Gyre, the Benguela Current, has two distinct branches: the Benguela Oceanic Current (BOC) and the Benguela Coastal Current (BCC). The BOC includes thermocline as well as intermediate waters. At the surface, it is replenished from two sources. There is a supply of Indian Ocean water which originates in the Agulhas Current region and slips into the South Atlantic Ocean around the Cape of Good Hope. Because Indian Ocean water is relatively warm, this source is called the 'warm water route.' The remaining water is subantarctic surface water added at the Subtropical Front, or intermediate water that enters the South Atlantic Ocean through Drake Passage, upwells into the thermocline, warms up and flows eastward with the South Atlantic Current.

This second source largely corresponds to the 'cold water route.' The northward flowing surface waters become warmer and, because of the high evaporation in the subtropics, they become saltier. In the western equatorial South Atlantic a fraction of the warm water flows southward with the Brazil Current to close the subtropical gyre. The remaining fraction crosses the equator and feeds the Gulf Stream and the North Atlantic Drift to reach the subpolar North Atlantic Ocean. Here these waters release their heat to the atmosphere and cool. Because of their high salinity, they become dense enough to sink to great depth in the Labrador and Nordic Seas and thus form NADW that eventually flows back into the South Atlantic. In the deep South Atlantic, NADW interacts with the northward flowing Circumpolar Deep Water (CDW). At about 45° S, the NADW divides the CDW into an upper Circumpolar Deep Water (UCDW) and lower Circumpolar Deep Water (LCDW) branch. The relatively warm and saline NADW occupies the depth interval between 1500 and 4000 m, while below 4000 m LCDW is encountered. The mixing zone between NADW and LCDW is marked by gradients in temperature, salinity, nutrient concentrations, and in the corrosiveness of the water with respect to calcium carbonate.

Late Quaternary Surface-Water Records

Sea-Surface Temperature

The distribution of SST in the South Atlantic is an important constraint for validating the results of coupled global climate models and serves as a boundary condition for simulating past ocean states with ocean general circulation models (e.g., Paul and Schäfer-Neth (2004)). SST reconstructions in the South Atlantic are based on transfer functions derived from assemblages of radiolaria, diatoms, or Foraminifera, alkenones, oxygen isotopes, Mg/Ca ratios, and calcium isotopes of planktic Foraminifera (for further information on paleoceanographic proxies, see Fischer and Wefer (1999)). Generally, SSTs in the tropical and South Atlantic were several degrees colder than today for much of the late Pleistocene. During the last interglacial and the preceding deglaciation (Termination II), however, temperatures were about 1.5 °C warmer than today in the subtropical South Atlantic and up to 3 °C warmer than today in the Southern Ocean (see Gersonde et al. (2004) and references therein). Most of the available time series indicate that SST in the South Atlantic and the Southern Ocean leads North Atlantic SST and ice volume at all orbital frequencies by several thousands of years. The early response of the Southern Ocean may be due to an early retreat of Antarctic sea ice in response to changes in summer insolation (e.g., Shemesh et al. (2002)). This early warming might then be transferred to the entire South Atlantic via advection.

Figure 1 Schematic representation of the large-scale, upper-level circulation in the South Atlantic Ocean (see also contributions in Wefer et al. (1996)) and locations of some important late Pleistocene paleoceanographic records cited in the text. Redrawn from Stramma L and England M (1999) On the water masses and mean circulation of the South Atlantic Ocean. *Journal of Geophysical Research* 104(C9): 20, 863–20, 883.

Another important effect on SST at millennial timescales is the so-called bipolar seesaw: caused by the massive decrease in the Atlantic northward heat transport, the surface northern North Atlantic cooled by several degrees Celsius, while the tropical Atlantic and South Atlantic warmed. The seesaw effect is most pronounced during deglaciations, when a large amount of freshwater is shed into the North Atlantic, disrupting the thermohaline circulation. Evidence that the seesaw effect is actually working on shorter timescales comes from high-resolution cores from the tropical Atlantic (Mix et al., 1986). Here, the anti-phased warming shows a clear two-step structure as expected from two meltwater pulses into the North Atlantic.

The best spatial coverage of SST reconstructions is available for the Last Glacial Maximum (LGM). In the South Atlantic, the most important features of the glacial distribution of SSTs are (1) a distinct cooling in the Southern Ocean, (2) a strong cooling in the upwelling region off Namibia, (3) a moderate cooling of 2–3 °C in the western tropical Atlantic (Figure 2; e.g., Gersonde et al. (2004)). The glacial cooling in the tropical and South Atlantic Ocean is generally explained as the result of

several combined effects: lower glacial CO₂ values, stronger upwelling and offshore displacement of upwelling zones, northward displacement of the frontal zones in the Southern Ocean (see discussion on Agulhas leakage, below), and advection of cold water as well as northward expansion of sea ice in the Southern Ocean.

Upper Ocean Stratification and Thermocline Depth

In the tropical Atlantic, mixed-layer thickness and thermocline depth are strongly related to wind strength and direction (see references in Wolff et al. (1999)). For this reason, reconstructions of mixed-layer and thermocline depth provide important constraints on the Pleistocene evolution of the equatorial wind system. On orbital timescales, thermocline depth in the eastern equatorial Atlantic is characterized by variations in the 23-ka cycle, whereas the western equatorial Atlantic thermocline shows a dominant periodicity in the 41-ka band (Figure 3; Wolff et al., 1999). The phase relationships with respect to

Figure 2 Austral summer sea-surface temperature anomaly (LGM – modern). Also indicated is the location of the estimated position of the Subtropical Front (STF), Sub-Antarctic Front (SAF), and Polar Front (PF), as well as the boundary of average winter sea-ice (AWSI) extent during the LGM. Arrows indicate sporadic expansion of summer sea ice (SSI) into the northern Weddell Basin. Compiled from various sources by Gersonde R, Abelmann A, Cortese G, et al. (2004) The late Pleistocene South Atlantic and Southern Ocean surface – A summary of time-series studies. In: Wefer G, Mulitza S, and Ratmeyer V (eds.) *The South Atlantic in the Late Quaternary: Reconstruction of Material Budgets and Current Systems*, p. 499. Springer.

insolation and ice volume suggest that thermocline fluctuations in the east are primarily driven by the intensity of the monsoon due to variations in low-latitude insolation. In contrast, changes in the thermocline depth in the western tropical Atlantic, which lead global ice volume at the 41-ka band by 3–4 ka, seem to depend on the strength of the SE trade winds in response to the meridional temperature gradients in the South Atlantic.

On shorter timescales, McIntyre and Molino (1996) proposed a link between tropical trade wind zonality and ice-raftering events (Heinrich Events) in the North Atlantic, based on the presence of the coccolithophore *Florisphaera profunda*, which is mainly controlled by thermocline depth. They report that maxima in mixed-layer depth in the eastern tropical Atlantic due to low easterlies correspond to Heinrich Events 1–5 in the North Atlantic (Figure 4). Warm water is released to the North Atlantic from the Caribbean warm water reservoir when tropical easterlies diminish, producing the rapid melting

of ice and hence Heinrich Events. A possible forcing of these events can be the precession cycle of insolation. Since the sun passes overhead twice a year in the tropics, two maxima in insolation exist during the course of a year. If climate is responding to the largest maximum of insolation, independent of the date it occurs during the year, it seems possible that precession is stimulating climate variability on half-precessional periods.

Evidence for higher seasonal stratification in the Southern Ocean, south of the modern Polar Front, comes from the radiolarian species *Cycladophora davisiana* (see references in Francois et al. (1997)). The only place where the modern abundances of this species are comparable to the glacial Southern Ocean is the Sea of Okhotsk, a marginal sea in the north-west Pacific. Here, the upper water column is characterized by a low sea-surface salinity layer with a strong temperature minimum at its base. Taking the Sea of Okhotsk as a modern analog, it has been proposed that the density stratification in the Southern Ocean was stronger than today during the LGM.

Figure 3 Comparison of the east-west thermocline slope with the tropical-subtropical SST evolution: (a) and (b) time series of alkenone-derived SSTs at core locations GeoB1523-1 and GeoB1028-5; (c) SST differences between cores GeoB1523-1 and GeoB1028-5; (d) thermocline differences (east-west slope) that were estimated by subtracting the thermocline depths of cores GeoB1105-4 and GeoB2204-2; and (e) SPECMAP stack indicative for global ice volume. From Wolff T, Mulitza S, Rühlemann C, and Wefer G (1999) Response of the tropical Atlantic thermocline to late Quaternary trade wind changes. *Paleoceanography* 14: 374–383, and references therein. Figure 4 Percentage of the coccolithophoridae species *Florisphaera profunda* in core RC2408 from the eastern equatorial Atlantic vs. ^{14}C age. Maxima in abundance are assumed to reflect times of a deep mixed layer in the eastern equatorial Atlantic. Modified from McIntyre A and Molino B (1996) Forcing of Atlantic equatorial and subpolar millennial cycles by precession. *Science* 274: 1867–1870.

However, the common view that the formation of southern source deep water was enhanced during glacials (see section on ‘intermediate and deep-water masses’) requires convection rather than stratification, at least during winter time.

Coastal Upwelling

Upwelling areas are of great importance for regional and global climate through their contribution to biological productivity and their interaction with winds, cloud formation, and precipitation. In the South Atlantic, the largest upwelling regions are located off Namibia, in the Benguela System. Today, these upwelling areas are fed by South Atlantic Central Water from about 200 m water depth. The planktonic foraminifer *Neogloboquadrina pachyderma* attains its highest abundance in modern coastal upwelling areas and thus has been used as an indicator for coastal upwelling (e.g., West et al. (2004)). In sedimentary records from the Benguela region, cyclic variations in the abundance of *N. pachyderma* indicate increased upwelling intensity in glacial maxima and precession maxima, and correlate well with the wind-strength record reconstructed from grain-size analysis (see references in West et al. (2004)). During glacial maxima, steep temperature gradients over the Southern Hemisphere led to strong SE trade winds and strong upwelling. Precession maxima caused a weak monsoonal circulation, more zonal SE trade winds, and strong coastal upwelling.

Off Namibia, the abundance of *N. pachyderma* also shows variability at sub-Milankovitch frequencies during the last 140 ka (Figure 5; Little et al. (1997)). Periods of high abundance in left coiling *N. pachyderma* (so-called ‘PS events’) correlate with North Atlantic Heinrich Events and Dansgaard–Oeschger cycles from Greenland Ice Cores. In accordance with the eastern tropical Atlantic thermocline variability, this suggests large-scale

Figure 5 Comparison between alkenone-derived sea-surface temperature, total pollen influx, abundance of the planktic foraminifer *Neogloboquadrina pachyderma* in core GeoB1711-4 and the deuterium record of the Vostok ice core. Redrawn from Shi N, Schneider R, Beug HJ, and Dupont LM (2001) Southeast trade wind variations during the last 135 ka: Evidence from pollen spectra in eastern South Atlantic sediments. *Earth and Planetary Science Letters* 187: 311–321, Elsevier.

global oceanographic or climatic teleconnections between the South and North Atlantic via the trade wind system.

A problem concerning most upwelling indicators is to distinguish between variations in local upwelling strength and changes in the 'preformed' characteristics of the source water mass of the upwelled water. For example, inferred changes in upwelling strength might simply reflect changes in the temperature or nutrient content of the ascending central waters that are related to processes in higher latitudes rather than variations in the local wind system.

Agulhas Leakage

Today, the Cape of Good Hope is an important site of warm water and salt import into the Atlantic Ocean (see section on 'present-day circulation of the South Atlantic' and Paul and Schäfer-Neth (2004)). This salt and heat import from the Indian and Atlantic Oceans (the so-called Agulhas leakage) is considered to be an important process to maintain the global thermohaline circulation. Changes in the amount of Agulhas leakage have been reconstructed by means of foraminiferal assemblages (Peeters et al., 2004). Foraminiferal records

suggest that the Agulhas leakage was enhanced during interglacials when increased strength of the Indian monsoon system promoted the transport of warm tropical waters feeding the Agulhas current (Figure 6). The highest Agulhas leakage took place during early deglaciations, suggesting a crucial role for Agulhas leakage in glacial terminations (Peeters et al., 2004). A major concern is whether foraminiferal assemblages in the Agulhas region really reflect Agulhas leakage or are just a manifestation of the general peak warming of the Southern Ocean during deglaciations (see above). Moreover, studies of coccolithophore assemblages do not suggest a significant change in Agulhas flow (Winter and Martin, 1990).

Freshwater Input

River runoff and precipitation in the tropical Atlantic

The Amazon and Congo rivers have the biggest flow in the world ($\sim 0.2 \cdot 10^6 \text{ m}^3 \text{ s}^{-1}$), and are responsible for a large part of the negative sea-surface salinity anomaly observed in the present-day tropical Atlantic Ocean. Information about freshwater run-off has been reconstructed either directly via the oxygen isotope composition of planktic Foraminifera or via

Figure 6 (a) Orbital eccentricity (black line) and precession (note inverted axis). (b) The Agulhas leakage fauna. Periods of maximum Agulhas leakage appear to be related to minima in precession (maxima in northern summer insolation). (c) The ratio of *G. truncatulinoides*/*N. pachyderma* dex. + *G. inflata* + *G. truncatulinoides* as a proxy for the distance of the STC relative to the position of the Cape basin record. High values indicate a southward position for the STC (note inverted axis). (d) The $\delta^{18}\text{O}$ of *Cibicides wuellerstorfi* (e–i). The Cape basin proxy records of Agulhas leakage (red line), global ice volume (black line), and SST (blue line) during the major late Pleistocene glacial Terminations I–V. From [Peeters FJC, Acheson R, Brummer G-JA, et al. \(2004\)](#) Vigorous exchange between the Indian and Atlantic oceans at the end of the past five glacial periods. *Nature* 430: 661–665.

indirect indicators, for example, the input of terrigenous components or freshwater diatoms. On orbital timescales monsoonal precipitation seems to follow the precessional cycle (see references in [Mulitza and Rühlemann \(2000\)](#)). Low Northern Hemisphere summer radiation during precession maxima suppresses the monsoonal circulation and leads to less precipitation over Africa and the tropical Atlantic. Actually, clay mineral proxies reveal that Congo River discharge and associated sediment input fluctuated in tune with precessional cycles of African monsoon intensity ([Gingele et al., 1998](#)). However, apart from the more gradual changes in monsoonal intensity on orbital time-scales, there is evidence for abrupt changes in freshwater supply during the last glacial period and during deglaciation. Measurements of elemental ratios in a high-resolution core from the continental slope off tropical Brazil show abrupt terrigenous sedimentation pulses that

suggest humid conditions and high surface runoff in north-east Brazil ([Figure 7; Arz et al. \(1998\)](#)). These pulses occur during times of ice rafting, reduced meridional overturning circulation, and low SSTs in the North Atlantic, the so-called Heinrich Events. Since SSTs in the tropical Atlantic are at a maximum during times of reduced overturning circulation (see section on ‘sea-surface temperature’) an increase of surface runoff off Brazil might be explained by a southward shift of the thermal equator and the associated Intertropical Convergence Zone ([Mulitza and Rühlemann \(2000\)](#) and references therein).

An alternative explanation might be an increased moisture supply with the SE trade winds. Today SE trade winds deliver intense precipitation to SE Brazil during Southern Hemisphere Winter. Increased tropical–subtropical temperature gradients in the South Atlantic during Heinrich Events might have led to

Figure 7 Comparison of the Ti/Ca and Fe/Ca ratio (Ti–Ca record scaled up fourfold) of cores GeoB 3910-2/3912-1 with the $\delta^{18}\text{O}$ record of the GISP2 ice core, the Heinrich Events, and the schematic longer-term cooling (Bond) cycles (see references in [Arz et al. \(1998\)](#)) (courtesy of Helge Arz).

stronger trade winds and more precipitation in the Brazilian hinterland. Since this increased supply of moisture should act at the expense of moisture supply to tropical Africa, we should expect that conditions are drier in tropical Africa during Heinrich Events. The isotopic composition of terrigenous plant lipids, extracted from a marine sediment core close to the Congo River mouth, indeed indicates that central African precipitation was reduced during Heinrich Event 1 and the Younger Dryas, contemporaneous with high differences in SSTs between the tropics and subtropics of the South Atlantic ([Figure 8](#); [Scheffuß et al. \(2005\)](#)). It must be noted, however, that organic components can have a significantly higher age than the surrounding sediment and may not be an optimal signal carrier for paleoclimatic proxies.

Meltwater and ice-rafted detritus (IRD)

The Quaternary history of meltwater and IRD input into the Southern Ocean has important implications for ice-sheet dynamics and the formation of intermediate and deep waters. The oxygen isotope composition of polar planktic Foraminifera together with records of IRD have been used to show that the region of the polar front has been covered by a meltwater lid containing significant contributions from melting icebergs in the period between 35 and 17 ka BP ([Labeyrie et al., 1986](#)). Cores from the southeast Atlantic Ocean show millennial-scale pulses of IRD delivery between 20 and 74 ka ([Figure 9](#); [Kanfoush et al. \(2000\)](#)). In this region, IRD events coincided with strong increases in NADW production and inferred warming (interstadials) in the high-latitude North Atlantic. Sea-level

rise or increased NADW production associated with strong interstadials may have resulted in destabilization of grounded ice shelves and surging in the Weddell Sea region. A recent compilation of IRD records by [Diekmann et al. \(2004\)](#), however, suggest that the temporal patterns of IRD distribution are not correlated over the entire Atlantic Sector of the Southern Ocean ([Figure 10](#)). In contrast to the southeast Atlantic Ocean, higher IRD fluxes are related to interglacial stages in the Weddell Sea. Marked IRD fluxes in the Bellingshausen Sea off the Antarctic Peninsula and in the southern and the northern Scotia Sea occur at glacial terminations and show small short-term spikes during MIS 3 and MIS 2. At present, it seems to be unclear whether the IRD signal really represents the dynamics of the Antarctic Ice Sheet, or is controlled by the temperature effect on the survival of icebergs or other sources of IRD from offshore Antarctica ([Diekmann et al., 2004](#)).

Sea Ice

Sea-ice variability plays a major role in global climate change through its effect on surface albedo and heat and salt balances in polar oceans. Recent sea-ice reconstructions in the Southern Ocean have mainly been done using the distribution of sea-ice diatoms (see [Gersonde et al. \(2004\)](#) and references therein). During the LGM, winter sea ice increased significantly by 60–70% with respect to the present ([Figure 2](#); [Gersonde et al. \(2004\)](#)). The summer sea-ice edge probably reached as far north as 55° S in the eastern Weddell Sea sector. In the southeast Atlantic Ocean, sea ice started to decline early

Figure 8 Deglacial-Holocene records of northern high-latitude and central African climate and SST variations in the tropical and subtropical Atlantic. Shown is (a) the GISP2 $\delta^{18}\text{O}$ record; (b) the plant-wax δD record from GeoB 6518-1 reflecting large-scale central African precipitation changes; (c) the plant-wax $\delta^{13}\text{C}$ record reflecting relative contributions from C3 and C4 plants; (d) the $\delta^{18}\text{O}$ record corrected for global ice volume and local temperature changes; (e) alkenone-derived sea-surface temperatures of core GeoB 6518-1; and (f) core GeoB 1023-5 from the subtropical South Atlantic and (g) the temperature difference between both cores. Triangles on lower axis indicate ^{14}C -AMS dates. The grey bar indicates the Younger Dryas period (YD; 12.9–11.6 ka BP). From Schefuß E, Schouten S, and Schneider RR (2005) Climatic controls on central African hydrology during the past 20,000 years. *Nature* 437: 1003–1006, and references therein.

Figure 9 (a) Ice-rafting (SA) events in the Atlantic sector of the Southern Ocean. Concentration of lithic components (blue), $\delta^{18}\text{O}$ of *N. pachyderma* (black), and abundance of Foraminifera (green) in core TTN057-13 and ODP Site 1094 at 53°S . Event SA0 occurs during the Antarctic Cold Reversal, as indicated by an increase in planktic $\delta^{18}\text{O}$ values during Termination I. Events SA1, SA3, and SA4 are associated with low planktic $\delta^{18}\text{O}$ values, which indicate either the influence of meltwater or warm SST. Events SA2 and SA4 are associated with large increases in foraminiferal abundance. (b) Similarities exist between the $\delta^{18}\text{O}$ record of the Greenland Ice Sheet Project 2 (GISP2) ice core (gold) and the benthic $\delta^{13}\text{C}$ (*Cibicidoides*) records of sediment cores RC11-83 (green) and TTN057-21 (blue). Prominent interstadials as defined in the GISP2 record are numbered, and the North Atlantic Heinrich (H) Events are indicated in relation to climatic events in the Greenland ice cores. South Atlantic IRD events SA0 through SA5 are expressed as peaks in the total lithic concentration in core TTN057-21 at 41°S (red). Events SA2 through SA5 are each associated with high benthic $\delta^{13}\text{C}$ values, indicating strong NADW production and inferred warming in the North Atlantic. From Kanfoush SL, Hodell DA, Charles CD, Guilderson TP, Mortyn G, and Ninnemann US (2000) Millennial-scale instability of the Antarctic ice sheet during the last glaciation. *Science* 288: 1815–1818.

during deglaciation at about 19 ka BP (Figure 11; Shemesh et al. (2002)). The early retreat of sea ice probably also affected the wind and precipitation regimes over the eastern South Atlantic. The patterns of terrigenous sedimentation on the continental margin off southwest Africa reveals coherent changes between Antarctic sea-ice extent and the southwest African winter rain since 45 ka BP, with enhanced winter rainfall and trade wind strength during periods of increased sea-ice presence (Stuut et al., 2004).

Productivity

Primary production is an important factor in the climate system because it influences the partitioning of carbon dioxide between ocean and atmosphere (see references in Rühlemann et al. (1999)). During the late Quaternary, high and variable productivity in the eastern equatorial Atlantic contrasts with relatively constant and low productivity in the West. During

cold substages, paleoproductivity was at a maximum in the east, whereas minimum values were attained in the West. This countercyclicity is probably due to the equatorial thermocline tilt with upwelling of nutrient-rich waters in the east and a contemporaneous nutricline deepening in the West due to the piling up of warm and nutrient-poor surface waters. Furthermore, there is evidence that the glacial central waters were depleted in nutrients relative to today. Since thermocline waters are a primary source of nutrients in oligotrophic areas, a lowering of their nutrient concentrations might also have contributed to lower paleoproductivity in the glacial western tropical Atlantic.

In the Southern Ocean, glacial productivity was lower south of the present-day Polar Front and increased to the North relative to today (Francois et al., 1997). Increased surface-water stratification south of the Polar Front may have contributed to the lowering of atmospheric CO_2 concentration during the Last Glacial Maximum.

Figure 10 Temporal and spatial variability of flux rates of ice-rafted detritus (IRD) recorded in sediment cores of the study area. Diagrams display IRD fluxes in $\# \text{cm}^{-2} \text{ka}^{-1}$ vs. age in ka (last 250 ka) with indication of average IRD value (italic number) and marine isotope stages (glacial stages in gray). Black circles on the map are proportional to average IRD values in the respective sediment cores. Late Quaternary Intermediate- and Deep-Water Records

Thermocline and Central Water Masses

The water masses of the permanent thermocline are known as central water masses. They originate at the subtropical convergences of both hemispheres and spread toward the equatorial regions. The circulation within the permanent thermocline is held to be responsible for transmitting the glacial cooling from high latitudes to the tropics through a stronger circulation

within a cooler and shallower thermocline (see references in Paul and Schäfer-Neth (2004)). For this reason, changes of the circulation within the thermocline can have important effects on tropical/subtropical productivity. Carbon isotope ratios of deep-dwelling Foraminifera indicate that nutrients were depleted in the thermocline during cold substages of the late Quaternary. Covariance between the $\delta^{13}\text{C}$ records of the deep-dwelling foraminifer *Globorotalia truncatulinoides* from the western equatorial Atlantic and the benthic foraminifer *Cibicides wuellerstorfi* from Caribbean intermediate water suggests that the upper part of the western equatorial Atlantic water column was largely composed of nutrient-poor central and intermediate waters of northern origin (Mulitza et al., 1998). This pattern might have been the result of a circulation mode in which sub-Antarctic surface waters formed nutrient-rich deep waters, rather than intermediate waters.

Benthic foraminiferal oxygen isotope ratios of a shallow sediment core recovered at 426 m water depth in the eastern tropical Atlantic indicate a rapid and intense warming of central waters during Heinrich Event H1 and the Younger Dryas (Figure 12; Rühlemann et al. (2004)). This warming is consistent with a reduced ventilation of cold intermediate and deep waters in conjunction with downward mixing of heat from the thermocline as predicted by the 'seesaw effect.'

Intermediate- and Deep-Water Masses

The deep South Atlantic is an important site to monitor changes in deep-water circulation, because it contains the mixing zone between the NADW and the southern source water masses. Most reconstructions of deep-water circulation rely on the carbon isotopic composition of benthic Foraminifera, which is inversely related to the nutrient concentrations and hence can be used to trace deep-water masses. Generally, the deep basins of the South Atlantic were occupied by cold, ^{13}C -depleted water masses during glaciations, whereas intermediate levels were dominated by ^{13}C -enriched water masses of northern origin (Duplessy et al., 1988). This pattern can be explained by a shallower overturning and a greater input of deep water from the Southern Ocean. Meanwhile, a wealth of cores provides a very detailed picture of the distribution of deep- and intermediate-water masses during the LGM (see compilation by Curry and Oppo 2005, Figures 13 and 14). These data indicate the presence of three distinct water masses in the glacial Atlantic Ocean: a shallow (~ 1000 m), southern source water mass with a $\delta^{13}\text{C}$ value of about 0.3–0.5‰, a mid-depth (~ 1500 m), a northern source water mass with an end-member value of about 1.5‰, and a deep (>2000 m), southern source water mass with $\delta^{13}\text{C}$ values of less than -0.2 ‰.

Deep-water properties in the South Atlantic are also influenced by millennial-scale climate signals (Figure 15). In a core from the deep Cape Basin, Charles et al. (1996) found abrupt changes in the carbon isotopic composition of benthic Foraminifera that lag Southern Hemisphere climate proxies by about 1.5 ka. This lag either reflects a very early response of Southern Hemisphere surface waters or is due to the seesaw effect that predicts warming of the South Atlantic during thermohaline circulation slowdown.

Figure 12 Evolution of benthic $\delta^{18}\text{O}$ in the cores M35003-4 ($12^{\circ}50' \text{ N}$, $61^{\circ}15' \text{ W}$; 1299-m water depth), and ODP1078 ($11^{\circ}55' \text{ S}$, $13^{\circ}24' \text{ E}$; 426-m water depth) during the last deglaciation and comparison to oxygen isotopes from the GISP2 ice core and atmospheric radiocarbon from sediments of Lake Suigetsu, Japan. Data from [Ruhlemann C, Mulitza S, Lohmann G, Paul A, Prange M, and Wefer G \(2004\)](#) Abrupt warming of the intermediate-depth tropical Atlantic caused by thermohaline circulation weakening: Evidence from paleoclimate data and model simulations. *Paleoceanography* 19: PA1025, (<http://dx.doi.org/10.1029/2003PA000948>). Reproduced/modified by permission of American Geophysical Union.

Figure 13 Holocene (solid line, solid symbols) and glacial (dashed line, open symbols) profiles of the stable isotopic compositions of benthic foraminifers *Cibicidoides* and *Planulina* from a vertical core transect on the Brazilian continental slope. Surface values represent stable isotope values of the planktonic foraminifer *G. ruber*. Several features of the Holocene and glacial water masses are depicted in the figures. The steep $\delta^{18}\text{O}$ gradient in the upper water column is controlled by the thermocline. The $\delta^{13}\text{C}$ profiles document changes in water-mass position and characteristics. The high $\delta^{13}\text{C}$ values associated with northern source waters shoaled during the glacial period to about 1500 m. A very steep bathymetric gradient in $\delta^{13}\text{C}$ below 1500 m was caused by gradual mixing between the northern source and southern source water masses at this location. [Curry WB and Oppo DW \(2005\)](#) Glacial water mass geometry and the distribution of $\delta^{13}\text{C}$ of ΣCO_2 in the western Atlantic Ocean. *Paleoceanography* 20: PA1017, (<http://dx.doi.org/10.1029/2004PA001021>). Reproduced/modified by permission of American Geophysical Union.

Figure 14 The distribution of $\delta^{13}\text{C}$ of dissolved CO_2 in the modern western Atlantic (top panel); and for the Last Glacial Maximum (bottom panel). A three-component model is proposed to explain the water-mass distribution and gradients. The patterns in the South Atlantic imply that the northern source water at 1,500 m penetrated as far as 30° S latitude. The penetration of the deep Southern Ocean water mass can be observed as far as 60° N. From Curry WB and Oppo DW (2005) Glacial water mass geometry and the distribution of $\delta^{13}\text{C}$ of ΣCO_2 in the western Atlantic Ocean. *Paleoceanography* 20: PA1017 (doi:10.1029/2004PA001021). Reproduced/modified by permission of American Geophysical Union.

Conclusions

Many of the processes that are at work in the present-day South Atlantic and Southern Ocean were affected by millennial- and orbital-scale climate changes during the late Pleistocene. The South Atlantic is not only reacting but also actively contributing to global climate change. For example, stratification and productivity of the Southern Ocean influenced the concentration of atmospheric CO_2 , and variations in sea-ice extent modified planetary albedo. The heat transport in the South Atlantic may be influenced by the changes in the input of warm water at the Cape of Good Hope. Furthermore, millennial-scale changes in wind-driven heat transport, potentially forced by changes in

orbital insolation, have been suggested as a potential trigger of ice-rafter events and deglaciations in the Northern Hemisphere. Future work must explore whether the tropical Atlantic can actually be a driver of abrupt climate change.

This article is reproduced from the previous edition, volume 3, pp. 1802–1815, © 2007, Elsevier B.V.

Introduction

The paleoceanography of the North Pacific is less well-known than that from other regions of the world's oceans, especially its Northern Hemisphere counterpart, the North Atlantic (see [Late Pleistocene North Atlantic](#)). The scarcity of records from the North Pacific has to do with the paucity or complete absence of carbonate in the deep-sea sediments in large parts of the Pacific (see [Dissolution of Deep-Sea Carbonates](#)). Most areas of the North Pacific lie below the carbonate compensation depth (CCD) which means that Foraminifera are absent from the sediments. In the modern North Pacific the CCD is as deep as 5 km in the central equatorial region and shoals to 3 km in the northern sub-Arctic Pacific. Even above those depths, in the lysocline (see [Dissolution of Deep-Sea Carbonates](#)) partial dissolution of carbonate shells is prevalent, which can lead to a bias of proxy records. However, in contrast to the Atlantic Ocean, the CCD was deeper by a few hundred meters during the last glaciation, resulting in somewhat better preservation of Foraminifera in glacial sediments ([Broecker, 1982](#)) and hence in improved conditions for paleoceanographic reconstructions. Unlike the North Atlantic, the North Pacific appeared as a passive ocean with little dynamics in ocean circulation and hydrography. This perception had already manifested itself when the ocean received its Latin name *mare pacificum*, 'peaceful sea,' by the explorer Ferdinand Magellan after his pioneering crossing of the Pacific Ocean. Oceanographically, the Pacific Ocean also appears relatively calm with its lack of deep-water formation, absence of large Arctic ice sheets throughout the late Pleistocene (see [Late Pleistocene Glacial Events in Beringia](#)) and the generally zonally aligned hydrographic pattern. However, the paleoceanographic records retrieved from the North Pacific reveal that the region was subject to a dynamic climate and oceanography during the late Pleistocene and before. Moreover, since the recognition of the far-field effects of El Niño, it has also become clear that oceanographic changes in the Pacific have the potential to substantially influence climate and environment on a global scale and most likely have done so in the past. For instance, the North Pacific provides moisture to the monsoon regions in Southeast Asia, to precipitation in North America, and to the growth of the Northern Hemisphere ice sheets. Furthermore, the North Pacific, due to its position at the far end of the global ocean circulation pathway, stores large quantities of nutrients and carbon in its subsurface waters. The importance of the Pacific Ocean as a whole is amplified by its sheer size and volume. With $180 \times 10^6 \text{ km}^2$ and volume of about $700 \times 10^6 \text{ km}^3$, the Pacific accounts for approximately half of the world's ocean volume, hence providing a huge storage capacity for all kinds of environmental substances, most importantly CO_2 .

Oceanographic Setting

Upper Ocean Circulation

The surface ocean circulation of the North Pacific is dominantly driven by the westerly and trade winds. The wind system generates the anticyclonic subtropical gyre and the cyclonic sub-Arctic gyre, which are separated from each other by the eastward flowing North Pacific Current at 30° – 42° N , the southern part of which is known as the Kuroshio Current Extension. The exact location of the North Pacific Current, an associated sub-Arctic–subtropical frontal system, moves around the mid-latitude area today and was almost certainly not stationary on paleoceanographic timescales. The same is therefore true for the location of the bifurcation of the North Pacific Current into the northward flowing eastern limb of the subpolar gyre and the southward flowing California Current.

Subsurface Ocean Circulation

No deep water is formed in the North Pacific today due to low salinity of the surface waters in the sub-Arctic gyre, which maintain a density contrast relative to the underlying waters, even if cooled close to freezing temperature. Pacific Deepwater below 1000 m therefore originates from southern source Circumpolar Deepwater that enters the northern basin along the western Pacific margin via the Deep Western Boundary Current. Gain of buoyancy through mixing with overlying less dense waters and, to a lesser extent, through geothermal heating ([Adcroft et al., 2001](#)) result in some rising of bottom waters to shallower deep-water levels and recirculation out of the North Pacific partly through the Indonesian Passage into the Indian Ocean and partly into the South Pacific, and back into the Antarctic Circumpolar Current, and from there through the Drake Passage into the Atlantic and Southern Ocean. The only subsurface water-mass forming in the North Pacific is the North Pacific intermediate water (NPIW). NPIW forms as a result of winter sea ice formation in the Sea of Okhotsk and mixing and subduction processes at the convergence of the subtropical Kuroshio and sub-Arctic Oyashio currents in the western North Pacific off Japan. The water mass spreads widely eastwards below the subtropical gyre at water depths between approximately 200 and 800 m. An important question of North Pacific paleoceanography is whether in past times, such as the Last Glacial Maximum (LGM), NPIW formation was increased, maybe even to the extent that it generated a deep-water mass of North Pacific origin. Deep-water formation in the North Pacific would alter inventories of oxygen and nutrients, and hence reduce the capacity of North Pacific waters to store carbon.

Occurrence of Paleoceanographic Records

The sedimentological characteristics described in the 'Introduction' determine the distribution of paleoceanographic records in the North Pacific. Most records are derived from the eastern and western continental margins and marginal seas. These locations are sufficiently shallow to preserve carbonate. Furthermore, sediments at these locations were often deposited at sedimentation rates of at least several centimeters per 1 ka, high enough to make them useful for paleoceanographic studies. North Pacific records from open ocean sites are rare. They are associated with seamounts that reach above the carbonate compensation depth, for example, on the Emperor–Hawaii Seamount chain, or singular seamounts under the Alaskan gyre in the sub-Arctic northeastern Pacific, or under the subtropical gyre in the western Pacific. It is evident that the Pleistocene paleoceanography of large regions in the central sub-Arctic and central subtropical North Pacific will never be investigated by means of carbonate-based geochemistry or micropaleontology.

The Paleoceanographic Record

Deep and Intermediate Water Records

Glacial–interglacial changes

Studies of deep and intermediate water paleoceanography in the North Pacific focus on changes in ocean circulation and hydrography. The Pacific has a significant capacity to store heat and various dissolved species of gases and salts. However, this capacity can vary with changing ocean circulation. Such variations may also have played a substantial role in global change during the late Pleistocene. Most studies of intermediate and deep water circulation in the North Pacific use the carbon isotopic composition of epibenthic Foraminifera shells ($\delta^{13}\text{C}_{\text{bent}}$), a proxy for the ventilation (oxygen content) of water masses (see **Nutrient Proxies, Carbon Cycle Proxies** ($\delta^{11}\text{B}$, $\delta^{13}\text{C}_{\text{calcite}}$, $\delta^{13}\text{C}_{\text{organic}}$, **Shell Weights, B/Ca, U/Ca, Zn/Ca, Ba/Ca**)). A number of other studies rely on the radiocarbon age difference ($\Delta^{14}\text{C}$) between benthic and planktonic Foraminifera to approximate the ages of subsurface water masses since their isolation from the atmosphere by sinking from the surface ocean into the ocean interior. Fewer studies are based on trace metal distribution in sediments and foraminiferal shells (see **Mg/Ca and Sr/Ca Paleothermometry from Calcareous Marine Fossils**) and on micropaleontological and sedimentological evidence. The overwhelming bulk of studies address the difference between the status during the LGM (ca. 18–24 ka) and the last deglaciation (ca. 18–11 ka) (see **Postglacial North Pacific**), while only singular studies reconstruct the development across the late Pleistocene (see Section '**Millennial-scale ventilation changes**').

$\delta^{13}\text{C}_{\text{bent}}$. Depth transects of benthic carbon isotope records (Duplessy et al., 1988; Keigwin, 1998; Stott et al., 2000; Matsumoto et al., 2002; Ohkushi et al., 2003) draw an overall consistent picture of glacial water column ventilation. Above about 2 km water depth $\delta^{13}\text{C}_{\text{bent}}$ values are as much as ca. 0.8‰ higher during the LGM than during the late Holocene, after addition of a global 'secular' value that adjusts for 0.3‰ lower average oceanic glacial $\delta^{13}\text{C}$ values. Below 2 km water

depth, the (corrected) glacial $\delta^{13}\text{C}_{\text{bent}}$ values were the same as or slightly lower (no more than 0.2‰) than today. Accordingly, $\delta^{13}\text{C}$ data suggest that the glacial North Pacific was better ventilated above 2 km, and – if anything – slightly less well ventilated in deep waters below 2 km. The finding of improved glacial ventilation above 2 km appears to be robust and of almost North Pacific-wide relevance. The result is supported by $\delta^{13}\text{C}$ transects from the far northwestern Pacific and Okhotsk Sea (Keigwin, 1998) as well as from a depth transect of seven cores from the northeastern Pacific California Continental Borderland (Stott et al., 2000). Matsumoto et al. (2002) compiled $\delta^{13}\text{C}$ data from the Pacific that were available at the time (exclusive of those from the California Borderland) and mapped the ventilation state of the Pacific Ocean in a zonally averaged profile. The most striking feature is a persistent zone of minimum ventilation in the Pacific, north of 20° N. The ventilation minimum was centered between 1 and 2 km water depth during the Holocene but more than 1 km deeper during the LGM (Figure 1). The relatively shallow depth of better glacial ventilation suggests a scenario in which intensified glacial NPIW production allowed waters to sink to about 1 km deeper than today and spread more widely through the North Pacific Ocean.

Cd/Ca. While $\delta^{13}\text{C}$ is a widely used proxy for the ventilation (oxygenation) state of water masses, it has its limitations in the clarity of interpretation. For example, in ocean regions or during times of high phytoplankton production, the $\delta^{13}\text{C}$ ventilation signal can be masked by locally high flux of fresh organic matter to the seafloor (the 'Mackensen effect'; see **Carbon Cycle Proxies** ($\delta^{11}\text{B}$, $\delta^{13}\text{C}_{\text{calcite}}$, $\delta^{13}\text{C}_{\text{organic}}$, **Shell Weights, B/Ca, U/Ca, Zn/Ca, Ba/Ca**), **Nutrient Proxies**). Complementary to the $\delta^{13}\text{C}$ records there exist a few trace metal-based reconstructions of the nutrient status of past bottom waters. Records of Cd/Ca ratios from benthic Foraminifera (see **Nutrient Proxies**) from water depths below 2700 m indicate that glacial nutrient concentrations were up to 50% lower than during the Holocene (Ohkouchi et al., 1994). These data seem to be in conflict with $\delta^{13}\text{C}_{\text{bent}}$ evidence for a slightly reduced ventilation of glacial deep waters. However, the Holocene Cd/Ca reference data in the records compiled by Ohkouchi et al. (1994) are based on only a few ambiguous values. Records with a better resolution, especially in the Holocene section, will be required to underpin the apparent disagreement between ventilation and nutrient proxy records.

$\Delta^{14}\text{C}$. As another independent way to reconstruct past circulation changes, some studies used the radiocarbon age difference between the surface and the bottom water, as determined from planktonic and benthic Foraminifera. The age difference provides a measure for the ventilation age of the subsurface water mass in which the benthic Foraminifera grew. The $\Delta^{14}\text{C}$ record of the North Pacific is patchy and not always unambiguous. With 2000 ± 450 yr being the average ventilation age measured for the glacial deep Pacific, the ventilation ages of glacial deepwater (3200 m water depth) were approximately 500 years older than today (Shackleton et al., 1988). On the contrary, glacial ventilation ages from water depths above 2000 m are slightly younger (Broecker et al., 2004a). The inferred scenario of better ventilated intermediate waters and less well-ventilated deep waters qualitatively match the

Figure 1 Meridional distribution of benthic foraminiferal $\delta^{13}\text{C}$ in the western Pacific Ocean. The lowest $\delta^{13}\text{C}$ indicated by shading is found in the deep North Pacific centered around 2000 m water depth during the Holocene and around 3000 m during the glaciation. Arrows indicate suggested circulation. The higher $\delta^{13}\text{C}$ in the upper 2000 m in the North Pacific reflect a local source of newly ventilated glacial NPIW, influx of modified Glacial North Atlantic Intermediate Water, or both. From Matsumoto K, Oba T, Lynch-Stieglitz J, and Yamamoto H (2002) Interior hydrography and circulation of the glacial Pacific Ocean. *Quaternary Science Reviews* 21: 1693–1704.

reconstructions from benthic $\delta^{13}\text{C}$. However, in an unsorted compilation of benthic-planktic $\Delta^{14}\text{C}$ data from the Pacific Ocean, Broecker et al. (2004b) demonstrate that the range of values span over 1 ka (Figure 2) for reasons of spatial heterogeneity, contamination with secondary calcite, bioturbational mixing of the sediment, and probably other causes. Future

studies using benthic-planktic $\Delta^{14}\text{C}$ as a ventilation proxy will therefore need to carefully choose suitable samples and exclude biasing factors.

Shell thickness of Foraminifera. A novel proxy for the estimation of water-mass chemistry is the shell thickness of planktonic Foraminifera, measured as the weight of shells of a

Figure 2 In the left-hand panel are the measurements of the $\Delta^{14}\text{C}$ (upper scale) for dissolved inorganic carbon (ΣCO_2) at three stations occupied during the GEOSECS survey. Also shown are the equivalent crude ages (lower scale) calculated assuming that the $\Delta^{14}\text{C}$ for surface mixed layer ΣCO_2 is 50‰. In the right-hand panel are crude age differences for coexisting glacial age benthic-planktic pairs (solid circles). The hatched region represents the present-day range of ages in the Pacific Ocean as a function of water depth. From Broecker WS, Clark E, Hajdas I, and Bonani G (2004b) Glacial ventilation rates for the deep Pacific Ocean. *Paleoceanography* 19: PA2002.

defined grain size. Assuming that the shell thickness decreases with gradual carbonate dissolution, one can approximate the corrosiveness, hence carbonate ion CO_3^{2-} concentration of bottom waters. A depth transect from the Ontong Java Plateau suggests higher-than-today CO_3^{2-} ion concentrations in the glacial western equatorial Pacific below 3 km water depth (Broecker and Clark, 2001). Higher CO_3^{2-} concentration in otherwise unchanged conditions would imply an improved ventilation of Pacific deep water. On a glacial-interglacial timescale, however, the lower concentration of CO_2 in the atmosphere may have biased the CO_3^{2-} reconstructions. On a global scale, it resulted in a shift of ocean chemistry toward higher CO_3^{2-} concentrations. Furthermore, it has recently been found that the initial thickness of Foraminifera shells is not constant as assumed, but varies according to surface water CO_3^{2-} saturation, which is linked to atmospheric CO_2 and other parameters. The shell weight record of the Pacific will therefore need re-examination in order to extract an unambiguous paleoceanographic signal.

Micropaleontological evidence. The species composition of the benthic Foraminifera community was investigated at sites of intermediate water depths at 1083 m and 2048 m off Japan (Ohkushi et al., 2003). Glacial assemblages are characteristic of well-oxygenated bottom waters compared with the low-oxygen assemblages found in Holocene sections. These results support geochemical evidence of better ventilation of glacial NPIWs to a depth of at least 2000 m. Moreover, the distribution of fossil abundances of the radiolarian species *Cycladophoria davisiana* provides information on potential regions of glacial deep convection and hence intermediate water formation (Ohkushi et al., 2003). Today, high abundances of this species are found mainly in the Okhotsk Sea, where deep convection forms part of the NPIW. In contrast to this, in last glacial sediments abundance maxima were found in the Bering Sea (Figure 3), suggesting that the Bering Sea contributed

substantially to the increased ventilation of intermediate depth waters in the glacial North Pacific.

Millennial-scale ventilation changes

The few existing records of changes in North Pacific deep ocean circulation before the LGM are restricted to the northeastern Pacific margin. Variations in the North Pacific are usually described in the context of rapid changes elsewhere, mostly of the Dansgaard-Oeschger and Heinrich events as recorded in Greenland and the North Atlantic (see Sub-Milankovitch (DO/Heinrich) Events). However, it should be kept in mind that these interbasin comparisons are in most cases limited by poor chronostratigraphic control, the improvement of which is presently a major challenge to high-resolution paleoceanography. A sediment core from 2712 m water depth off Oregon provides a benthic foraminiferal $\delta^{13}\text{C}$ record of deep-water ventilation over the last 60 ka (Lund and Mix, 1998). Increases in $\delta^{13}\text{C}$ on the order of 0.2‰ display repeated millennial-scale events of improved ventilation during stadial episodes (cold events in Greenland), in particular, during the pronounced stadials marked by Heinrich melt-water events in the North Atlantic (Figure 4). The millennial-scale pattern of deep ocean ventilation in the Pacific was therefore suggested as being opposite to the pattern in the Atlantic. This could mean that during cold stadials, deep water formed in the North Pacific down to at least 2700 m. Such deep-water formation could have been enabled by higher surface-water salinity in the North Pacific in response to reduced freshwater import due to cooler Atlantic surface waters and decreased intensity of the Southeast Asian summer monsoon. Alternatively, faster turnover of Pacific deep waters, driven by Southern Ocean winds, may have compensated for suppressed North Atlantic deep water production during stadial intervals.

Figure 3 Comparison between (a) present and (b) last glacial distribution patterns for *Cycladophora davisiana* in the North Pacific deep-sea sediments indicating favorable conditions for deep convection. From Ohkushi K, Itaki T, and Nemoto N (2003) Last Glacial–Holocene change in intermediate-water ventilation in the Northwestern Pacific. *Quaternary Science Reviews* 22: 1477–1484.

Records of intermediate water ventilation come from the California Margin, most famously from the Santa Barbara Basin, where sediments are partially laminated. Laminations prevail in sections representing the Holocene and the interstadials, while sediment sections coeval with the cold stadials in Greenland and the North Atlantic are bioturbated (Behl and Kennett, 1996). These sedimentary structures, alongside a suite of other proxy evidence including assemblage changes of benthic Foraminifera and of redox-sensitive elements, suggest that suboxic to anoxic conditions during (the Holocene) interstadials alternated with high oxygen conditions in the Santa Barbara Basin during times of cold stadials in Greenland and the North Atlantic (Cannariato and Kennett, 1999). The combined records from the Oregon and California margins suggest

that deep and intermediate waters in the North Pacific had a similar history with respect to millennial-scale ventilation changes during the last glacial cycle.

The Surface-Water Hydrographic Record

As in the deep-water record, reconstructions of surface-water hydrography have focused on the LGM and even allowed spatial mapping of the sea-surface temperature (SST) field for that time slice (Climate Long-Range Investigation, Mapping, and Prediction (CLIMAP), Multiproxy Approach for the Reconstruction of the Glacial Ocean Surface (MARGO)). For other time periods the coverage of paleoceanographic reconstruction is fragmentary and relies on individual records.

Figure 4 Benthic foraminiferal $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ in core W8709A-13A compared to the percentage of a cool-water planktonic Foraminifera species in a North Atlantic core. Shaded areas represent cold (stadial) intervals in the North Atlantic. Millennial-scale $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ maxima in the North Pacific generally correspond to stadial conditions in the Atlantic. From Lund DC and Mix AC (1998) Millennial-scale deep-water oscillations: Reflections of the North Atlantic in the deep Pacific from 10 to 60 ka. *Paleoceano-graphy* 13: 10–19.

The Last Glacial Maximum

The CLIMAP project (CLIMAP Projekt Members, 1981) produced a map of SST during the LGM (Figure 5). The reconstructions were based on faunal (mostly planktonic foraminiferal) assemblages that were processed with a statistical algorithm, a so-called transfer function. One intriguing result was that only parts of the glacial North Pacific were reconstructed as significantly colder than today, such as the sub-Arctic North Pacific, the western Pacific margin, and the equatorial Pacific, while the subtropical North Pacific was reconstructed as up to 2 °C warmer than today.

With the availability of more and better-dated data, improved statistical techniques, and additional proxies, the task was re-addressed by a joint effort called MARGO. Their Foraminifera-based reconstruction refined some of the earlier CLIMAP results (Kucera et al., 2005), such as a more southerly position of the sub-Arctic front, the contraction and maybe even cooling of the Western Pacific Warm Pool, and a substantial (>3 °C) cooling of the eastern equatorial Pacific and the southward flowing California Current off the US coast. Contrary to CLIMAP, the MARGO reconstruction does not provide conclusive evidence for LGM warming anywhere in the Pacific (Figure 6). This Foraminifera-based reconstruction is generally

consistent with alkenone-derived LGM SST (Rosell-Mele et al., 2004; Figure 7).

The shallow lysocline in the North Pacific results in an imperfect preservation of foraminifera shells in most regions and in large areas where carbonate-based reconstructions are not possible, such as for the North Pacific subtropical gyre. However, a suite of sediment cores from shallow water depths well above the lysocline from off Hawaii provides invaluable paleotemperature data (Lee et al., 2001). SST estimates from foraminiferal assemblages and from alkenones both confirm that the subtropical gyre was indeed colder by 1–3 °C during the LGM (Figure 8).

Marine Isotope Stage 5

The Earth's orbital configuration during the peak of the last interglacial (marine isotope stage 5e; Eemian, around 130–120 ka) was different from the Holocene interglacial, in particular, with summer insolation higher in the Northern Hemisphere (see *Astronomical Theory of Paleoclimates*). Accordingly, the CLIMAP reconstruction of the Eemian surface ocean found that SST in the North Pacific were predominantly higher by 1–3 °C than during the Holocene. Since then, other records with complementary methods lend further support

Figure 5 Map of summer SST differences between reconstructions for the Last Glacial Maximum (LGM) and for the late Holocene. Figure taken from Kucera et al. (2005). From CLIMAP Project Members (1981) Seasonal reconstructions of the Earth's surface at the Last Glacial Maximum. *Geological Society of America Map and Chart Series*: 1–18.

Figure 6 Differences between LGM annual SST in the Pacific estimated from foraminifer assemblages and modern measured SST (World Ocean Atlas, 1998). The SST values represent averages of the estimates from three different methods (ANN, SIMMAX, and RAM). Samples where the maximum difference in SST estimates among the four techniques is $< 2^{\circ}\text{C}$ are indicated by solid circles (highest reliability), between $2\text{--}4^{\circ}\text{C}$ by solid diamonds (medium reliability), and $> 4^{\circ}\text{C}$ by open circles (lowest reliability). Figure taken from Kucera et al. (2005).

Figure 7 Change in annual mean sea-surface temperature between the Last Glacial Maximum and the present derived from alkenones using the U_{37}^K index. From Rosell-Melé A, Bard E, Emeis K-C, et al. (2004) Sea surface temperature anomalies in the oceans at the LGM estimated from the alkenone U_{37}^K index: Comparison with GCMs. *Geophysical Research Letters* 31: L03208.

Figure 8 Comparison of sea-surface temperature (SST) variations over the last 30 ka reconstructed from sediment core PC17 off Hawaii. SST were derived from planktonic Foraminifera assemblages using the Modern Analog Technique and from alkenones using the U_{37}^K index.

that the Eemian was warmer than today. Examples come from the western equatorial Pacific including the South China Sea with at least 1 °C, from the California Current with 2–3 °C (Kreitz et al., 2000; Figure 9), and off central Japan with 3 °C higher SST. The long record from the California Current furthermore suggests that, at least regionally, the Eemian interglacial period was among the warmest periods in the North Pacific since at least the mid-Pleistocene.

Millennial-scale variability

Millennial-scale hydrographic variability during the last glacial is documented along the eastern and western North Pacific margins and in the western sub-Arctic gyre, and usually compared to concurrent changes in Greenland and the North Atlantic (Heinrich and Dansgaard-Oeschger events; see Sub-Milankovitch (DO/Heinrich) Events). In the South China Sea (Wang et al., 1999), the Sulu Sea (Dannenmann et al., 2002), and south of the Philippines (Stott et al., 2002) in the tropical–subtropical western Pacific, hydrographic changes

mostly concern sea surface salinity (SSS) as indicated by $\delta^{18}O$ of planktonic foraminiferal calcite. Western Pacific surface waters were more saline (saltier) during cold (stadial) times in the North Atlantic and fresher during times of relative Atlantic warmth (Figure 10). Various records, especially speleothems from caves in eastern China, have compellingly demonstrated that southeast Asian summer monsoon precipitation goes along with warmth in the North Atlantic. Hence, monsoonal variability is a prime candidate to explain the paleosalinity oscillations in the western Pacific. More relevant to the open ocean tropical Pacific are changes in local precipitation caused by past changes in the Walker circulation associated with ENSO variability. The paleosalinity record would imply a weakened Walker circulation associated with more frequent or stronger El Niño conditions during stadials. Validation of this scenario will require more well-dated millennial-scale records from the western and eastern equatorial Pacific, of parameters sensitive to ENSO, for example, thermocline depth and phytoplankton productivity.

Different from the paleosalinity record, millennial-scale variations of SST observed at western Pacific low latitudes were small (Dannenmann et al., 2002; Figure 10). Only one planktonic foraminiferal record from the Okinawa Trough in the East China Sea points to systematic cooling of ca. 2 °C during the time of Heinrich melt-water events in the North Atlantic (Li et al., 2001). However, in the northeastern Pacific, several paleohydrographic records off the US west coast also show millennial-scale fluctuations of remarkable resemblance with records from Greenland and the North Atlantic. In particular, the cores from the Santa Barbara Basin off California display such detailed similarity between planktonic foraminiferal isotopic and assemblage changes with the temperature changes in Greenland that quasi-synchronicity can be inferred (Hendy et al., 1999). This very important finding has promoted the awareness of paleoceanographic coupling between ocean basins and the concept of global-scale teleconnections in paleoclimatology in general. Temperature variations in the Santa Barbara Basin deduced from the planktonic $\delta^{18}O$ record reached amplitudes of up to 5 °C, or even up to 8 °C including brief temperature overshoots at the beginning of warm phases. Alkenone-derived SST variations from a nearby site with a more open-ocean setting off Point Conception were on the

Figure 9 Alkenone SST from off California (DP Site 1020) SST and $\delta^{18}\text{O}$ from ODP site 677 for reference. Age model from tuning site 1020 to site 677 $\delta^{18}\text{O}$. Interglacial periods are shaded. order of 3–4 °C (Seki et al., 2002; Figure 11). Further north, from the California Current off Oregon, SST records based on radiolarian assemblages also display millennial-scale variations of 2–3 °C that can be correlated to the Greenland temperature pattern (Pisias et al., 2001). The ongoing discussion about mechanisms for the Atlantic–Pacific signal transfer include mid-latitude atmospheric circulation changes due to an oscillating morphology of the Laurentide ice sheet, and oceanic circulation changes in response to Atlantic–Pacific water vapor transport or far-field effects of global oceanic overturning. One single record from the sub-Arctic North Pacific – from the western gyre – also reflects millennial-scale hydrographic changes during the last glacial cycle (Kiefer et al., 2001). A multi-proxy SST record based on faunal composition, $\delta^{18}\text{O}$ and Mg/Ca ratios of planktonic Foraminifera suggests that SST varied by at least 3 °C during marine isotope stage 3 (Figure 12). In contrast to the more southerly sites, however, SST was apparently out of phase with the Greenland/North Atlantic temperature pattern. The stratigraphy of this core relies on the Pacific–Atlantic correlation of characteristics of the geomagnetic record that are assumed to be globally synchronous (see [Geomagnetic Excursions and Secular Variations](#)). An out-of-phase temperature pattern in the subarctic Pacific

suggests a dominant oceanic control on SST, such as a shallowing of the mixed layer in response to basin-wide changes in ocean circulation or changes in the local hydrography.

The Surface-Water Biogeochemical Record

Glacial–interglacial changes

In order to understand the role of the North Pacific in the sequestration or emission of atmospheric CO_2 , it is important to develop our knowledge of past changes in nutrient status and phytoplankton productivity. The modern sub-Arctic North Pacific and the central eastern equatorial Pacific are both ocean regions of open-ocean upwelling where supply of nutrients is not readily utilized for phytoplankton production, making those regions net sources for CO_2 to the atmosphere. It is important to reconstruct past CO_2 budgets of these regions and learn whether these regions were past sinks or sources for atmospheric CO_2 . Late Pleistocene records of phytoplankton productivity changes reveal a large-scale pattern of glacial–interglacial changes with opposing patterns between open ocean regions of the subarctic and the tropical–subtropical North Pacific. In the eastern and central tropical Pacific, Barite accumulation records over the last 3–4 glacial cycles (350 and

Figure 12 (c–e) Sea-surface temperature (SST), (a) sedimentation rates, and (b) geomagnetic paleointensity records at sub-Arctic northwest Pacific ODP site 883 between 29 and 65 cal ka BP compared to (f) the GISP2 $\delta^{18}\text{O}$ temperature record. From Kiefer et al. (2002).

450 ka) show that the export of fresh organic matter (export productivity) was about twice as high during glacials than during interglacials (Paytan et al., 1996). Most other proxies support this observation (Paytan et al. (2004), and references therein). This implies equatorial upwelling of nutrient-rich subsurface waters driven by stronger glacial trade winds or increased nutrient utilization and changes in ecosystem structure. The increased upwelling may have been a significant glacial source of CO_2 to the atmosphere, although the balance between export production and upwelling is what determines the new CO_2 flux. Higher glacial productivity is also repeatedly reported from sites below the Kuroshio Extension in the sub-Arctic–subtropical transition zone and often attributed to increased glacial dust fertilization, while a southward shift of the transition zone and associated southward expansion of nutrient-rich sub-Arctic surface waters provides an additional explanation. In the western sub-Arctic Pacific and its marginal seas, the Okhotsk Sea and Bering Sea, export productivity was decreased during glacial periods. A record of biogenic Barium concentration strongly suggests that export production fluctuated in parallel with temperatures over Antarctica and the Southern Ocean (Jaccard et al., 2005; Figure 13). Records

available from the sub-Arctic eastern Pacific do not reveal a clear pattern. Better stratification of the upper ocean inhibiting nutrient supply from below, extensive sea ice, and light limitation were all suggested as possible causes for low glacial productivity and for counteracting any possible iron fertilization in these domains (see review of Kienast et al. (2004)). If the glacial North Pacific was indeed better stratified, this would imply that the outgassing of CO_2 during the process of subsurface-water upwelling was reduced or prevented, hence contributing to the lower glacial concentrations of CO_2 in the atmosphere.

Millennial-scale variability

Evidence for millennial-scale productivity changes in concert with the Dansgaard–Oeschger temperature oscillations over Greenland (see Sub-Milankovitch (DO/Heinrich) Events) comes from the California margin cores (see Section ‘Millennial-scale variability’), where increased export productivity during interstadials was proposed to have contributed to or even to account for the low bottom-water oxygen content in the Santa Barbara Basin at intermediate water depths. Alternation between predominant La Niña conditions with a

Figure 13 Biogenic barium concentration at North Pacific ODP site 882 (red) and the Antarctic ice core δD record at Vostok station (gray) over the past 150 ka, illustrating the strong correlation between productivity in the North Pacific and temperatures over Antarctica. shallow nutricline during warm intervals on the one hand, and predominant El Niño conditions with a deep nutricline hampering algal productivity during cold intervals on the other hand, was discussed as a plausible explanation. In contrast to this, the record of biogenic Barium from the western sub-Arctic Pacific correlates surprisingly well with temperatures over Antarctica (Jaccard et al., 2005). The proposed control mechanism for productivity involves increased polar stratification inhibiting the supply of nutrients from below into the sunlit zone during global cold times. However, at present it is still not clear how the temperature signal was transferred from the Southern Hemisphere to the Northern Hemisphere high latitude Pacific.

Postglacial Indian Ocean

P D Naidu, National Institute of Oceanography, Dona Paula, India

Introduction

The summer monsoon is the dominant climatic feature of the Indian Ocean tropics and the adjacent continent. Boreal summer is characterized by high solar radiation that causes intense heating over northern India and the Tibet Plateau. This pattern of heating causes ascending air flow and the development of an intense low-pressure cell that is centered over Asia around 30° N (Figure 1). The atmospheric pressure gradient between the Asian Continent and the cooler southern Indian Ocean induces large-scale meridional overturning with the lower circulation limb being the strong low-level southwesterly summer monsoon winds of the western Indian Ocean. The convergence of these air masses and their uplift due to heating and orographic steering cause seasonal monsoon rains (Figure 2). By contrast, the winter season of the Asian sector is characterized by low solar radiation, cold temperature, and northeasterly winds, which flow from the cold Asian continent toward the Arabian Sea. These continental winter monsoon winds carry little moisture and have relatively low velocity. Monsoon rainfall in India is highly variable. The northeastern region, the western slopes of the Western Ghats, and parts of the Himalayas have very high rainfall of around 2000 mm annually. The eastern part of the peninsula extending up to the northern plain receive around 1000–2000 mm rainfall, while the area from western Deccan up to the Plains of the Punjab gets around 100–500 mm rainfall. Thus the unique monsoon circulation in the Indian Ocean and associated rainfall over Asia have two fundamental regional effects: (1) socioeconomic and agricultural development in the densely populated Asian countries and (2) the biogeochemistry of the Indian Ocean sediments.

Pre- and Postglacial Changes

The last deglaciation was not a smooth transition from one climate state to another but rather occurred in a series of steps. Recent evidences suggest that the deglacial warming was initiated ~19 ka BP in the Indian Ocean and alike $\delta^{18}\text{O}$ trend prevailed in the Antarctica and Indian Ocean record (Figure 3; Naidu and Govil, 2010). The $\delta^{18}\text{O}$ records of the Indian Ocean exhibit a two-step deglaciation model that included two phases of rapid ice melting separated by a brief period of climate stability (Figure 4; Peeters et al., 1999); however, sea surface temperature (SST) show a gradual warming during deglaciation. Earlier it was believed that only in the circum-Atlantic region deglaciation was interrupted by a brief return to colder conditions, the so-called Younger Dryas event centered at about 12 ka BP. A Younger Dryas event is also documented in the $\delta^{18}\text{O}$ records of the Indian Ocean sediment records, but conspicuous cooling was not noticed during Younger Dryas in the Indian Ocean.

The carbon and oxygen isotope records of benthic Foraminifera show that the water-column structure of the Indian

Ocean during the Last Glacial Maximum (LGM) was marked by the presence of a deep front separating intermediate and deepwater masses with very different characteristics (Kallel et al., 1988). The intermediate water temperature and carbon isotope values were similar to those of today. By contrast, the deepwater was cooler than now by at least 1.5 °C, more depleted in ^{13}C , and poorly oxygenated. The vertical salinity/ $\delta^{18}\text{O}$ gradient in the northern Indian Ocean during the LGM was similar to the modern one. The sharp deep front between intermediate and deepwater is thus best explained by the decrease in deepwater temperature in the Indian Ocean and development of a deep thermocline. The hydrological boundary between deep and intermediate waters became suppressed after deglaciation.

Salinity Contrast

Oxygen isotopic ratios ($\delta^{18}\text{O}$) of *Globigerinoides ruber* in the northern Indian Ocean reveal a pattern similar to that of salinity conditions. In the Bay of Bengal, the $\delta^{18}\text{O}$ values decrease progressively toward the mouth of the Ganges, Brahmaputra, Irrawaddy River system, clearly reflecting the salinity pattern. The general north–south $\delta^{18}\text{O}$ increase in the Arabian Sea also fits the salinity pattern and reflects the strong evaporation excess in this basin (Figure 5(a)). The $\delta^{18}\text{O}$ difference between glacial and Holocene indicates a sharp salinity contrast from the glacial to Holocene in the Bay of Bengal (Figure 5(b)). During the Holocene from south to north, *G. ruber* $\delta^{18}\text{O}$ values decrease by 1.1‰ in the Bay of Bengal and increase by 0.8‰ in the Arabian Sea, whereas mean annual sea surface salinity decreases by 3 PSU in the Bay of Bengal and increases by 1.5 PSU in the Arabian Sea (Duplessy, 1982). During the LGM, reduction in the $\delta^{18}\text{O}$ gradient observed in the Bay of Bengal and the Andaman Sea is associated with a decrease in river discharge due to weaker southwest monsoon.

A marked increase in *G. ruber* $\delta^{18}\text{O}$ gradient is observed in the Arabian Sea. This strong glacial isotope gradient, which is larger than 1‰, is not related to the geographical distribution of the SST which is more uniform than today but indicates a strong salinity increase from south to north due to more evaporation. The difference between the oxygen isotope ratios of planktic Foraminifera of LGM and Holocene (Figure 5(b)) shows that the southwest monsoon was weaker than today but that the northeast monsoon was stronger. However, it would be difficult to interpret the $\delta^{18}\text{O}$ of planktic foraminifer as a proxy of monsoon precipitation in the Indian Ocean, as $\delta^{18}\text{O}$ of planktonic Foraminifera is influenced by temperature and the $\delta^{18}\text{O}$ of seawater where the latter covaries with salinity and, on millennial time scales, global ice volume. Subsequently, these problems are circumvented and $\delta^{18}\text{O}_{\text{sw}}$ were reconstructed by removing the effect of temperature (temperature estimates by Mg/Ca ratios in foraminifer) and global ice volume effect from the $\delta^{18}\text{O}$ of planktic Foraminifera. Such studies from

Figure 1 Atmospheric circulation during the summer months, regional wind patterns, north–south pressure gradient and cyclonic circulation around the Asian low-pressure center. Modified from Clemens S, et al. (1991) Forcing mechanisms of the Indian Ocean monsoon. *Nature* 353: 720–725.

Figure 2 Pattern of rainfall during peak monsoon along the Western Ghats of India.

the Arabian Sea show heavy $\delta^{18}\text{O}_{\text{sw}}$ values during the last glacial period than the present day reflecting more evaporation and less precipitation (Anand et al., 2008; Dahl and Oppo, 2006). Similarly, $\delta^{18}\text{O}_{\text{sw}}$ variability in the Bay of Bengal (Govil and Naidu, 2011) and Andaman Sea (Rashid et al., 2007) also points out that Indian Ocean monsoon intensity was stronger during early Holocene and weaker during last glaciation.

SST Changes

SST estimates based on the faunal composition, alkenones, and magnesium/calcium ratios show about 3–4 °C regional cooling in the Indian Ocean during the glacial maximum as compared to the Holocene. Seasonal SST reconstructions show

that summer and winter SST were 1.2 and 2.6 °C cooler, respectively, during the LGM than in the Holocene. Earlier SST estimates based on the alkenones in the Arabian Sea document a rather stable SST changes in the range of 27.1–27.7 °C during the Holocene (Rostek et al., 1998). Recent reconstructions of SST variations based on the Mg/Ca ratios in planktic foraminifer document ~2 °C fluctuations during the Holocene in the Bay of Bengal and Arabian Sea (Naidu and Govil, 2010). Similarly, the monsoon upwelling regions of the western Arabian Sea also shows a temperature change of 2 °C during the Holocene (Naidu and Malmgren, 2005; Saher et al., 2007). In general, both summer and winter SST estimates show greater magnitude of fluctuations during the last glaciation compared to the Holocene (Figure 6). However, within the Holocene, a 2 °C change in summer SST has occurred mainly due to the variation of upwelling intensity. In the tropical Indian Ocean, last deglacial warming was initiated between 18 and 19 ka. Before the onset of deglacial warming, 20 ka BP is marked with a rise of 1–2 °C temperature (Figure 7). Overall, a 4 °C rise in SST from 19 to 14 ka BP documented in the Indian Ocean and significant cooling was not noticed during Younger Dryas.

Recently Ganssen et al. (2011) have analyzed $\delta^{18}\text{O}$ analyses on individual specimens of planktonic foraminifer species (*G. ruber* and *Globigerina bulloides*) from a sediment core off the Somalia, which reveals that seasonal SST has fluctuated between 13 and 11 °C, with greater seasonal SST change in the Holocene than in last glacial period.

Outflows into the Indian Ocean During the Deglaciation

Western Pacific, Red Sea, and Persian Gulf waters flow into the Indian Ocean as surface water outflow at the sill depths ranging from 100 to 300 m. These three outflow waters have significant influence on the hydrography at the thermocline depth in the Indian Ocean. The outflow has varied through time depending on the sea-level changes. The outflow of western Pacific, Red Sea, and Persian Gulf waters was suppressed during the LGM due to lower sea levels. A vigorous flow of Red Sea outflow into the Arabian Sea was reconstructed for 2 ka BP before a major monsoon intensification caused the cessation of deepwater formation from 15.5 to 7.3 ka BP (Figure 8; Naqvi and Fairbanks, 1996). Similarly, during glacial periods, the Bab el Mandab Strait was reduced to <20 m in depth or even completely closed off so that advection of Red Sea waters to the Arabian Sea was drastically reduced, if not completely cut off.

Monsoon Variability

Various biogeochemical proxies have been used to reconstruct the summer monsoon variability over geological time scales. This section discusses the variability of monsoon during the postglacial period (mainly the Holocene). After a weak summer monsoon activity during the LGM, the initiation of strengthening monsoon activity began around 15 ka BP, which coincides with the Northern Hemisphere deglaciation. Monsoon activity further increased from 12 ka BP and reached maximum intensity between 9 and 6 ka BP. Thereafter, it decreased from 5 to 1.2 ka BP (Figure 9; Naidu and Malmgren, 1996). As a consequence of strong monsoon rainfall, the

outflow of the rivers draining the Himalayan Mountains increased at the end of the deglaciation, and it was larger than today during early and mid-Holocene. About $5 \times 10^{12} \text{ m}^3$ of sediment was deposited in the Bengal Basin from 11 to 7 ka BP when the southwest monsoon was strong (Goodbred and Kuehl, 2000). Furthermore, the development of Ganges–Brahmaputra River Delta began 11 ka BP, when rising sea level flooded the Bengal Basin, thereby trapping most of the river discharge on the inner margin. Recent studies based on $\delta^{18}\text{O}_{\text{sw}}$ (which is more reliable proxy for monsoon rainfall) reconstructions from the Bay of Bengal and the Arabian Sea also supports that initiation of SW monsoon around 15 ka and reduction of monsoon rainfall during Younger Dryas (Anand et al., 2008; Rashid et al., 2007).

Ultra high-resolution record of monsoon variability during the time span of 1 ka reveals that the monsoon wind strength increased during the past four centuries as the Northern Hemisphere warmed (Anderson et al., 2002). This suggests that the warming trend may directly affect the monsoon, and the observed link between Eurasian snow cover and the southwest monsoon persists on a centennial scale. However, comparison of all India rainfall data with the Northern Hemisphere air temperature anomalies over last 100 years do not support that global warming effect on the Indian rainfall at decadal time scale.

Coherent Occurrence of Abrupt Climate Shifts in the North Atlantic and Monsoon Changes

During the last Ice Age, the Indian Ocean summer monsoon exhibited abrupt changes that were closely correlated with millennial-scale climate events in the North Atlantic region, suggesting a causal link. The amplitude of abrupt changes in the North Atlantic region was smaller during the Holocene than in the glacial period; hence, the Holocene epoch is considered as a stable phase. A high-resolution study from the Oman Margin documented seven distinct intervals of weak summer monsoon during the Holocene (Figure 10). These weaker summer monsoon phases are correlated with the millennial-scale cooling in the North Atlantic. On the other hand, monsoon maxima have occurred in several pulses during which the North Atlantic was warmest, including the most recent climate changes from the Medieval Warm Period to the Little Ice Age (Gupta et al., 2003). This makes a strong case linking the monsoon events of the Indian Ocean with that of North Atlantic climate shifts. Thus, the link between North Atlantic climate and the Asian monsoon is a long-term aspect of global climate.

Similar coherent changes between monsoon variability and high-latitude climate events have also been reconstructed prior to deglaciation. For example, sediment cores from the northeastern Arabian Sea show laminated, organic-carbon-rich bands, reflecting strong monsoon-induced biological productivity that correlate with mild interstadial climate events in the northern North Atlantic region. In contrast, periods of lowered southwest monsoonal intensity, indicated by bioturbated, organic-carbon-poor bands, are associated with intervals of high-latitude atmospheric cooling and the injection of melt water into the North Atlantic basin. Arabian Sea monsoon records suggest that Dansgaard–Oeschger and Heinrich events are strongly expressed in low-latitude monsoon climate variability. Sediment records from the Pakistan Margin suggest that the rapid Dansgaard–Oeschger and Heinrich-style events known from Greenland and the North Atlantic are also a significant component also of low-latitude climate variability during the past 110 ka due to millennial to centennial fluctuations in the intensity of southwest monsoonal circulation (Schulz et al., 1998). Thus, several lines of evidence suggest a synchronicity between monsoon variability of the Indian Ocean and high-latitude climate change during pre- and post-deglaciation times.

Monsoon Forcing Mechanisms After Deglaciation

Linking the climatic events of the high latitudes to the tropical climatic events in general and Asian monsoon events in particular gained much importance during last decade. Synchronicity has been demonstrated between changes of monsoon intensity and variation of temperatures in Greenland Ice Cores and North Atlantic. Are these mere coincidences or is there a physical mechanism to explain a link between high-latitude climate changes and monsoons? None of these studies, however, has shown a connection between SST changes in the North Atlantic and the tropical latitudes and Indian monsoon system in quantitative terms. Two propositions have been made to address the forcing mechanism of the monsoon at millennial and centennial time scales after deglaciation.

Figure 6 Annual, summer, and winter sea surface temperatures variations at the ODP Site 723A from the western Arabian Sea. These temperatures were estimated using artificial neural networks based on planktic foraminiferal census data. Modern sea surface temperature for annual, summer, and winter is shown by a straight gray line. Annual solar insolation at 20°N curve in the panel (a) is shown by a gray line. Thin gray lines in the panel (b) and (c) are minimum and maximum error bars of temperature estimations. Reproduced from Naidu PD and Malmgren BA (2005) Seasonal sea surface temperature contrast between the Holocene and last glacial period in the western Arabian Sea (Ocean Drilling Program Site 723A): Modulated by monsoon upwelling. *Paleoceanography* 20: PA1004, <http://dx.doi.org/10.1029/2004PA001078>.

Figure 7 Sea surface temperature variations in the eastern Arabian Sea derived by the Mg/Ca ratios in planktic foraminifer species *Globigerinoides ruber*. Reproduced from Govil and Naidu (2010) Evaporation–precipitation changes in the eastern Arabian Sea for the last 68 ka: Implications on monsoon variability. *Paleoceanography* 25: PA1210, 11 pp.

Figure 8 Changes of $\delta^{13}\text{C}$ in benthic Foraminifera of intermediate water depth (650 m) from the NW Arabian Sea. The $\delta^{13}\text{C}$ shifts between Holocene and last glacial was much smaller than the global mean. Thus the observed changes of $\delta^{13}\text{C}$ in a sediment core from the Gulf of Aden reflect changes of Red Sea outflow. The increase in $\delta^{13}\text{C}$ represent greater outflow of Red Sea water and vice versa. Modified from [Naqvi WA and Fairbanks RG \(1996\)](#) A 27 000 year record of Red Sea outflow: Implications for timing of post-glacial monsoon intensification. *Geophysical Research Letters* 23: 1501–1504.

El Niño teleconnection

The interdecadal variation of the Indian monsoon rainfall is strongly correlated with the interdecadal variations of various indices of El Niño-Southern Oscillation (ENSO; [Krishnamurthy and Goswami, 2000](#)). The decrease in the Indian monsoon rainfall associated with the warm phases of ENSO is due to an anomalous regional Hadley circulation with descending motion over the Indian continent and ascending motion near the equator sustained by the ascending phase of the anomalous Walker circulation in the equatorial Indian Ocean. However, inverse relationship between the ENSO and the Indian summer monsoon has broken down in recent decades ([Kumar et al., 1999](#)). A southeastward shift in the Walker circulation anomalies associated with ENSO events may lead to a reduced subsidence over the Indian region, thus favoring normal monsoon conditions. Additionally, increased surface temperatures over Eurasia in winter and spring, which are a part of the mid-latitude continental warming trend, may favor the enhanced land-ocean thermal gradient conducive to a strong monsoon. Therefore, Eurasian warming in recent decades helps to sustain the monsoon rainfall at a normal level despite strong ENSO events.

The Last deglaciation monsoon records of the Arabian Sea also show synchronicity between monsoon changes and high-latitude climate. It has been proposed that the Pacific El Niño is capable of effecting remote parts of northern and Southern Hemisphere and that Asian monsoon and Pacific El Niño are coupled systems ([Sirocko, 1996](#)). Such low and high-latitude teleconnections could be mediated through the Jet Stream of the upper troposphere and lower stratosphere.

Figure 9 Variation in mass accumulation rates of planktonic Foraminifera *G. bulloides* through the last 19000 years BP in ODP Site 723A from the western Arabian Sea. These microfossil indices are sensitive to upwelling intensity and may, therefore, be employed to monitor the SW monsoon variability. Reproduced from [Naidu PD and Malmgren BA \(1996\)](#) A high resolution record of late Quaternary upwelling along the Oman Margin, Arabian Sea based on planktonic Foraminifera. *Paleoceanography* 11: 129–140.

Solar activity

There is sound evidence that the intensity of the summer monsoon has fluctuated dramatically in the past, varying with precessional changes in the distribution of solar radiation reaching the earth. The Holocene epoch has spanned half of precessional cycle. During this time the Northern Hemisphere has changed from having maximum seasonality approximately 11 ka BP, when the summer solstice was aligned with perihelion, to a minimum today. The tropical seasonal monsoons are highly influenced by precessional variations in insolation, resulting in a wetter tropical climate as monsoon intensity increases. Furthermore, variation of solar output has been suggested as the driver of both the North Atlantic cycles (Bond et al., 2001) and the variation of monsoon precipitation in Oman (Neff et al., 2001). Intensity of the Indian monsoon is found to have decreased during periods of solar minima during the last millennium suggesting solar control on the Indian monsoon on multidecadal time scale (Agnihotri et al., 2002).

Dipole

A dipole mode in the Indian Ocean has been noticed in late 1990s: a pattern of internal variability with anomalously low SST off Sumatra and high SSTs in the western Indian Ocean, with accompanying wind and precipitation anomalies (Saji et al., 1999). This air-sea interaction process is unique and inherent in the Indian Ocean and is shown to be independent of the ENSO. The dipole mode accounts for about 12% of the SST variability in the Indian Ocean. The $\delta^{18}\text{O}$ and Sr/Ca composition of modern corals from the Mentawai Island clearly show distinct cooling signals in coral Sr/Ca which represent Indian Ocean Dipole events from 1961 to 1994.

The Holocene coral records preserve similar signals and provide the first evidence that the Indian Ocean Dipole has operated since at least the mid-Holocene (Abram, 2001). These Dipole events also occurred during times when mean ocean SST and rainfall conditions were different from today, showing that the Indian Ocean Dipole is a robust climatic feature that persists in a range of mean climatic states. The fossil coral records also provide evidence that the Indian Ocean Dipole system can operate independently of the ENSO, with dipole events continuing in the mid-Holocene when ENSO is thought to have been substantially weaker than today.

Productivity Variations

The biological productivity of the Indian Ocean is highly seasonal, being highest during the summer monsoon, followed by the winter monsoon and the inter monsoon season. Flux of carbonate, organic carbon, and foraminiferal tests is tightly coupled to monsoon intensity in the western, central, and eastern Arabian Sea, as shown by sediment trap studies. However, in the past, the relationship between monsoon and productivity was not straight forward. All paleoproductivity records from the western Arabian Sea show that productivity was higher after deglaciation (Holocene) driven

by strong southwest monsoons. In the eastern Arabian Sea, the productivity proxies such as organic carbon and alkenones show higher values during the LGM as compared to the Holocene; therefore, it was suggested that in the eastern Arabian Sea paleoproductivity is predominantly linked to variation in the NE monsoon winds (Rostek et al., 1998). Recent studies from the eastern Arabian Sea also support that overall high productivity during last glacial period than in Holocene, within the last glacial period a drop in productivity corresponds Heinrich Events, which again suggests a teleconnection between the productivity in the Arabian Sea and North Atlantic climate (Singh et al., 2011). However, it is emphasized here that there is no consistent agreement between various productivity proxies from different regions of the eastern Arabian Sea. Therefore, the differences between productivity proxies such as calcium carbonate and organic carbon concentrations in the eastern Arabian Sea between glacial and interglacials are attributed to regional differences in sedimentation rates, dilution, and preservation, which modify the signal of carbonate and carbon production (Guptha et al., 2005).

Oxygen Minimum Zone Variability

The northern Arabian Sea is one of the few regions in the open ocean where thermocline water is severely depleted in oxygen. This intense oxygen minimum zone (OMZ) results from high rates of oxygen consumption in the water column due to high surface water productivity values and organic particle fluxes combined with a moderate rate of thermocline ventilation by Central Indian Ocean Water. The intensity of the OMZ has varied through orbital and suborbital time scales, and this variability is thought to be driven by changes in surface water productivity and the depth of winter mixing. Periods with a pronounced OMZ (such as the present times) are characterized by shallow winter mixing, while annual surface water productivity is high. Periods with a weak OMZ, on the other hand, are marked by low annual surface water productivity conditions and winter mixing that is deeper than today. Similar to OMZ, the denitrification process in the Arabian Sea also varied through time during glacial and interglacial periods. Isotopic fractionation of nitrogen associated with denitrification enriches $^{15}\text{NO}_3^-$ as $^{14}\text{NO}_3^-$ and is preferentially converted to gaseous products. As denitrification proceeds, the residual nitrate in the oxygen-deficit subsurface waters become progressively enriched in $^{15}\text{NO}_3^-$. A consistent pattern of heavy $\delta^{15}\text{N}$ and high accumulation rates of biogenic components during the Holocene and lighter $\delta^{15}\text{N}$ and low accumulation rates of biogenic components during glacials have been documented in the Arabian Sea (Figure 11) (Ganeshram et al., 2000). Reconstruction of denitrification at centennial time scale from the coastal eastern Arabian Sea document a substantially weakened denitrification during Little Ice Age (AD 1500 to 1750), as a result weak SW monsoon (Agnihotri et al., 2008). This suggests that the denitrification process of the Arabian Sea is tightly coupled with the SW monsoon strength in both millennial and centennial time scale. The influence of anthropogenic inducing of atmospheric CO_2 and subsequent absorption by ocean over last two centuries has resulted in ocean acidification in the Arabian Sea as evident from the presence

Figure 10 The abundance of *G. bulloides* in the sediment is relatively proportional to the monsoon activity in the Arabian Sea and percentage of hematite from the North Atlantic sediment reflects the temperature changes in the North Atlantic. Therefore, here the *G. bulloides* is used to infer the monsoon intensity and hematite percentage as proxy for temperature. The vertical gray bars indicate intervals of weak monsoon that coincides with the cold temperature in the North Atlantic. Modified from Gupta AK, et al. (2003) Abrupt changes in the Asian southwest monsoon during the Holocene and their links to the North Atlantic Ocean. *Nature* 421: 354–356.

Figure 11 Benthic Foraminifera $\delta^{18}\text{O}$, $\delta^{15}\text{N}$ and organic-carbon content from a sediment core along western continental margin of India (MD76-131). The $\delta^{15}\text{N}$ and organic-carbon profiles indicate higher productivity and denitrification during the Holocene as compared to the last glacial period. Modified from Ganeshram RS, et al. (2000) Glacial–interglacial variability in denitrification in the world’s oceans: Causes and consequences. *Paleoceanography* 15: 361–376.

of thin-shelled Foraminifera in the sediment trap samples as compared with late Holocene (Moel et al., 2009).

The organic-carbon record from the Indian margin suggests lower productivity during glacial periods. This phenomenon has also been reconstructed for the Oman margin, based on a glacial age decline in biobarium and organic-carbon accumulation recorded in regional sediments. It has also been found that the lowest oxygen levels in the oxygen minimum correlates with productivity maxima in sedimentary records from the Pakistan margin. Thus, glacial decreases in productivity and denitrification in the Arabian Sea are attributed to the weakening of the summer monsoonal winds that drive seasonal upwelling and dominate mean annual export production. This substantiates that lower denitrification during glacial periods in the Arabian Sea could have resulted from a decrease in upwelling and the settling flux of organic material through the water column.

Therefore, the $\delta^{15}\text{N}$ record and associated data indicate that the Arabian Sea has exhibited large, climate-driven variations in denitrification, probably forced directly by changes in

the intensity of the summer monsoon and associated upwelling (Altabet et al., 2002). The denitrification in the Arabian Sea has been reported as being between 12 and 30 Tg years⁻¹ and thus could account for up to 10–25% of total marine denitrification.

Conclusions

The initial onset of climatic change in the Indian Ocean at the end of the glacial is marked around 15 ka BP. SST reconstructions of the Indian Ocean show 3–4 °C regional cooling during the LGM as compared to the Holocene. A striking contrast between LGM and Holocene concerns monsoon strength, productivity, denitrification, outflows of the red Sea, and Indonesia through flow. A prominent synchronicity between the strength of monsoon and high-latitude climate has been documented for the intervals before and after deglaciation. These teleconnections between high and low latitudes may be driven by the ENSO. The variability of biological productivity, monsoon strength, and denitrification are strongly coupled in the Indian Ocean. Strong monsoon during the Holocene results in higher productivity, which in turn triggers the denitrification in the Arabian Sea. It appears that monsoon, productivity, and denitrification are greatly influenced by high-latitude climate changes.

Introduction

The most recent warm interglacial period, the Holocene, can be characterized as 10 ka of relative climatic stability compared to the previous 100 ka of Earth's history, the last glaciation ([Figure 1](#)). This notion of stability disappears however when examining the magnitude and duration of Holocene climate changes on their own merit ([Figure 2](#)). Numerous high-resolution paleoclimate reconstructions using tree-ring, lake-sediment, and ice-core data document that the Holocene was beset by global changes in temperature and hydrologic variability that persisted for up to several centuries. Most notably, the North Atlantic region experienced a sustained cold event approximately 8.2 ka that lasted for up to 400–600 yr in certain regions ([Figure 3](#)). In the Norwegian Sea, for example, local cooling has been detected as early as 8.6 ka ([Rohling and Palike, 2005](#)). This gradual cooling was suddenly intensified 8.2 ka when two North American glacial lakes flooded into the North Atlantic, slowing the formation of North Atlantic Deep Water and its associated northward heat transport for several centuries. The resulting multicentury cold event has now been recognized throughout the Northern Hemisphere as the '8.2-ka event'.

Less abrupt centennial-scale climate shifts have also punctuated the Holocene, resulting in three subdivisions based on climatic changes. These include (1) the pre-Boreal/Boreal climate transformation (from 10 to 8.5 ka), (2) the relatively warm Hypsithermal interval from 8.5 to 5 ka, and (3) the most recent Neoglacial cooling from 5 ka to today. Whereas these names have largely been abandoned, it is widely agreed that changes in the Earth's precession, obliquity, and eccentricity, in addition to changes in the global thermohaline circulation, have contributed to North Atlantic climatic variability during the Holocene.

Identifying subtle Holocene climatic variations in marine records can be challenging for several reasons. First, the record of Holocene oceanographic conditions is often preserved in only a few centimeters of poorly compacted marine silt and clay. In order to decipher SST and water-mass changes that may have persisted for a century or less, one must identify regions where sediments have accumulated rapidly over the past 10 ka, and use precision coring techniques that can preserve the delicate sediments that rest on the sea floor. Second, past oceanographic conditions must be interpreted from a combination of temperature, salinity, and density proxy data at a variety of depths in the water column. In addition, changes in these water properties could result from a number of climatic forcings, including changes in solar insolation, thermohaline circulation, and surface winds.

Today, warm and relatively fresh surface waters are transported from the equatorial Atlantic to the NE North Atlantic

along the Gulf Stream, North Atlantic Drift, and Norwegian Atlantic Current ([Figure 4](#)). Along this northward journey, evaporation and cooling increase the density of surface waters until they become unstable and sink at several key locations in the NE Atlantic ([Figure 5](#)). The conversion of surface water to deepwater releases heat from the ocean to the atmosphere, bathing nearby locations in anomalous warmth that buffers the entire region from nearby cold Arctic air masses.

Variations in solar insolation and the amount and location of deep-water production have led to regional climate oscillations during the Holocene. In this article, we review detailed records of major Holocene (Postglacial) variability in SST and ocean circulation within a select group of high sediment-accumulation-rate basins in the North Atlantic.

SST Variations

Holocene SST reconstructions are more spatially complete in the North Atlantic compared to other oceans, although still primarily limited to high sediment-accumulation-rate, near-shore basins. Pioneering research seeking to identify a long-term trend in upper ocean temperatures focused on reconstructing SSTs for 9 and 6 ka, using planktonic foraminiferal assemblages ([Ruddiman and Mix, 1993](#)). Calibration studies in the 1950s and 1960s had demonstrated that certain groupings of planktonic Foraminifera are highly correlated to SST, in addition to salinity and water-column nutrients ([Morey et al., 2005](#)). [Ruddiman and Mix \(1993\)](#) found no discernible pattern of past SST variability in the North Atlantic and questioned both the methodology used for quantitative reconstructions and the age control associated with variable sediment-accumulation rates.

A subsequent study of reconstructed summer SST for 6 ka, using a variety of methods (diatom assemblages, marine mollusks, and dinoflagellate cysts), found that warmer conditions (+1–4 °C relative to today) inundated the Norwegian Sea, Hudson Bay, Baffin Bay, Nares Strait, Davis Strait, Labrador Sea, and Greenland Sea during a time when summertime insolation was approximately 7% higher than today ([Kerwin et al. \(1999\)](#), and references therein). This trend of warmer-than-present SSTs during the early to middle Holocene is perhaps best illustrated in core MD952011 ([Calvo et al., 2002](#)) from the Norwegian Sea where maximum SST warming (+2 °C relative to today) accompanied the Holocene Thermal Maximum between 8.6 and 5.5 ka, followed by a gradual cooling to today's temperatures.

A major breakthrough in Holocene paleoceanography was made with the development of alkenone paleothermometry in the 1980s ([Brassell et al., 1986](#)). Alkenones are long-chained

Figure 1 Time series of calcium concentration in Greenland over the past 110 ka. Calcium concentration is a proxy for the amount of dust in the atmosphere over Greenland and illustrates the relative stability of the Holocene compared to the last glacial period. From <http://www.gisp2.sr.unh.edu>; modified from Mayewski PA, Meeker LD, Whitlow SI, et al. (1994) Changes in atmospheric circulation and ocean ice cover over the North Atlantic during the last 41 000 years. *Science* 263: 1747–1751.

The top panel shows the $\delta^{18}\text{O}$ record (proxy for temperature) from Greenland over the past 10 ka (Grootes et al., 1993). The bottom panel shows variations in EOF1 which is a composite measure of major chemistry representing atmospheric circulation (O'Brien et al., 1995).

ketones synthesized as membrane lipids by certain kinds of algae that are well preserved in marine sediments (see [Alkenone Paleothermometry Based on the Haptophyte Algae](#)). The alkenone unsaturation index U_{37}^K is considered to be a robust proxy for SST because the algal organisms synthesizing alkenones must live in the photic zone, where their growth temperature is closely tied to SST. By measuring the alkenone unsaturation ratio preserved in a wide array of marine-sediment cores, a detailed picture of past surface ocean conditions may be possible (Bard, 2001).

Alkenone-based SST reconstructions from seven high-accumulation sediment cores in the North Atlantic (north of 35°N) and the western Mediterranean Sea show a cooling trend of $0.15\text{--}0.27^\circ\text{C}$ per thousand years over the past 10 ka (Marchal et al., 2002). These records are significant in that they

span a large area of the NE North Atlantic from 36° to 74°N latitude (Figure 6). This surface ocean cooling trend is also apparent in three non-alkenone reconstructions from the Labrador Sea and Iceland Basin (Figure 7). Isotopic analyses ($\delta^{18}\text{O}$) on two foraminiferal species, in combination with dinocyst assemblage data, suggest that SSTs have been cooling steadily since the early Holocene (Solignac et al., 2004). These $\delta^{18}\text{O}$ records each show more high-frequency variability than the alkenone-derived records, likely because of the sensitivity of isotopes to changes in sea-surface salinity as well as surface temperature (Solignac et al., 2004).

In contrast to the records from the high-latitude North Atlantic, alkenone data from sediment cores in the low-latitude North Atlantic (south of 30°N), eastern Mediterranean, and northern Red Sea (Figure 8) suggest that SSTs gradually warmed

during the Holocene (Rimbu et al., 2003). This apparent contradictory pattern of SST variability within the North Atlantic can be explained by opposing trends in the mean annual insolation forcing, which decreases throughout the Holocene in the high latitude North Atlantic but increases at low latitudes (Figure 9). Opposite SST trends in the eastern and western Mediterranean may reflect the continuous weakening of the North Atlantic Oscillation (NAO) from the early to the late Holocene (Duplessy et al., 2005; Rimbu et al., 2003).

Ocean Circulation Variations

During the last glaciation, many of the large global millennial-scale climate oscillations coincided with alterations in thermohaline circulation in the North Atlantic. Understanding variability in thermohaline circulation during the Holocene has more recently become an objective of paleoclimatologists, leading to the refinement of a variety of proxies. In the Labrador Sea, for example, $\delta^{18}\text{O}$ measurements on planktonic Foraminifera, combined with analog reconstructions using dinocyst assemblages, have been used to document past thermohaline properties of the upper water column (Solignac et al., 2004). Similarly, grain size variations in deep ocean sediments have been correlated to changes in the speed of bottom currents south of Iceland (Bianchi and McCave, 1999). The concentration of

carbonate from the Bermuda Rise (Keigwin and Jones, 1989) and changes in the export flux of coccoliths to the south of Iceland (Giraudeau et al., 2000) have been shown to reflect instabilities in surface circulation. Carbon isotopic variations in benthic Foraminifera from the Feni Drift (Oppo et al., 2003) suggest that relatively high $\delta^{13}\text{C}$ values indicate a higher

proportion of North Atlantic Deep Water relative to Southern Ocean water. Th/Pa ratios from sinking particles that accumulated in Bermuda Rise sediments reflect the export of water from the North Atlantic basin and show a brief episode of significantly reduced deep-water formation during the mid-Holocene (McManus et al., 2004).

Paleoceanographic reconstructions using these techniques (and others) suggest that millennial-scale and shorter-term fluctuations in thermohaline circulation were a prevalent feature of the Holocene. Whereas changes in solar activity have been linked to a 1.5-ka cycle of North Atlantic hydrologic variability (Bond et al., 2001) and possibly century-scale solar variability, other, shorter-term variations result from changes in global thermohaline circulation, meltwater fluxes, and the general atmospheric circulation of the North Atlantic region. Although many more well-dated proxy records are needed to establish a complete picture of Holocene ocean circulation variability, the well-dated records that exist reveal several consistent patterns. In particular, during the early Holocene, deep-water formation increased in the northeastern corner of the North Atlantic, coincident with a period of reduced deep-sea ventilation in the Labrador Sea in the western North Atlantic.

In the eastern North Atlantic, where the Barents Sea borders the Arctic Ocean (Figure 10), oxygen isotopes from planktonic and benthic Foraminifera provide insight into Holocene thermohaline circulation changes. Today, cold and relatively fresh Arctic water enters the Barents Sea from the north and tends to remain at the surface. In contrast, relatively warm ($>1^\circ\text{C}$) and saline (>35 per mil) Atlantic water arrives from the south via thermohaline circulation. This northward-flowing Atlantic water sinks near the Barents Sea, but only to an intermediate depth, because the bottom waters are occupied by extremely cold and dense water that originates from brine rejection during sea-ice formation (Duplessy et al., 2005).

As a result, the hydrologic profile of the Barents Sea is strongly dependent on the amount of Atlantic water that reaches the area and settles in as intermediate water, due to thermohaline circulation.

Isotopic variations in sediment core ASV 880 from the Franz Victoria Trough (northern Barents Sea) provide a high-resolution record of deep-sea ventilation in the NE North Atlantic (Duplessy et al., 2005, and references therein). This record shows that thermohaline circulation and deep-water production peaked from 7.8 to 6.9 ka. During this time, Atlantic water occupied the entire water column as very little Arctic water sank along the Barents Sea Shelf. This was also the time of maximum Holocene SSTs, due in part to the strong northward flow of warm Atlantic water and the enhanced summer insolation forcing during the Holocene Thermal Maximum. After 6.9 ka, the flux of Atlantic water into the Arctic decreased and surface temperatures cooled. This reduction in thermohaline circulation created thicker and more extensive sea ice in winter. Subsequent brine rejection created a cold, dense water mass which promptly began to sink to the bottom of the Barents Sea, progressively replacing the Atlantic water that had occupied the entire water column. More recent hydrologic variability in the Barents Sea seems to correlate to long-term changes in the NAO, rather than the thermohaline circulation (Blindheim et al., 2000).

Figure 10 Location map of the Barents Sea.

During the early to middle Holocene, equally dynamic ocean circulation changes were occurring in the western North Atlantic. Here the analog method has been used to match fossil dinocyst assemblages from Holocene sediments to modern dinocyst assemblages from nearly 700 sites in the mid- to high-latitude North Atlantic and Arctic oceans (Solignac et al., 2004). This approach allows quantitative reconstructions of SST, sea-surface salinity, and sea ice cover. Two sediment cores from the western North Atlantic show that the surface of the Labrador Sea was relatively warm and fresh from 10 to 7.5 ka, when the final remnants of the Laurentide Ice Sheet melted away (Solignac et al., 2004). After 7.5 ka, surface temperatures decreased and the salinity increased as the meltwater flux from Laurentide Ice Sheet was eliminated. Surface temperatures and salinity then remained relatively stable throughout the remainder of the Holocene, with minor fluctuations representing changes in the relative strength and position of nearby minor ocean currents. One of the more significant fluctuations occurred about 7 ka, when the surface of the Labrador Sea became dense enough that intermediate water formation intensified. This period of enhanced deep-sea ventilation in the western Atlantic came at a time when warm Atlantic waters entering the Barents Sea diminished, resulting in a slowing down of the thermohaline circulation along the NE North Atlantic route. This pattern illustrates the antiphase nature of thermohaline circulation changes in the western and eastern North Atlantic.

Other records from high sediment-accumulation regions between the Labrador Sea and Barents Sea reinforce the dynamic nature of Holocene ocean circulation variations. A thick accumulation of Holocene sediments at the Rockall Plateau provides a well-dated record of oceanographic variability along the North Atlantic Drift. Core NA87-22 (Duplessy et al., 1992; Samthein et al., 1994) shows that changes in sea-surface salinity and density accompanied shifts in the amount of meltwater that reached the North Atlantic and the pattern of atmospheric circulation. Like the records from the Labrador Sea,

surface-water salinity near the Rockall Plateau was relatively low from 9 to 7.5 ka because of large meltwater contributions from the Laurentide Ice Sheet and the discharge of glacial lakes Agassiz and Ojibway during the 8.2-ka event. During the middle Holocene (7–5 ka), salinity increased after the final disappearance of the Laurentide Ice Sheet. Another major decline in surface water salinity began about 4.5 ka and lasted until 2.8 ka. This more recent Holocene salinity minimum is not associated with a meltwater peak because the Laurentide Ice Sheet had completely melted by this time. Rather, it appears to result from large-scale changes in atmospheric circulation that increased the amount of precipitation relative to evaporation over the North Atlantic (Duplessy et al., 2005).

Core MD99-2254 from the Greenland Rise shows several short intervals of cold, low-salinity surface water during the past 8 ka (Solignac et al., 2004). These pulses have been interpreted as increased fluxes of Arctic water from the north. They are consistent with periodic penetrations of cold surface waters and increased drift ice in the Nordic and Labrador Seas that were first described by Bond et al. (1997) and subsequently observed in numerous other studies throughout the Atlantic basin. Relatively fresh Arctic water in the Greenland Rise would have formed a buoyant surface-water layer that strengthens the stratification of the upper water column. This strong stratification would have limited the diffusion of heat through the entire water column and led to more warming of the surface layer in the summer and more cooling in the winter. Early work suggested that this persistent millennial-scale cycle was tied into fluctuations in the energy output of the Sun, and Bond et al. (2001) suggest that solar fluctuations, despite being small as an overall forcing, can affect climate in the North Atlantic over the entire Holocene.

It is worth noting that spatial variations in surface-water conditions are not solely driven by changes in insolation and thermohaline circulation. Recent research has documented that variations in the NAO are a persistent feature of the Holocene climate in the North Atlantic. When the NAO

index is high, strong winds from the west accompany a vibrant northward-flowing Norwegian current (Blindheim et al., 2000). The prevailing winds push Atlantic water toward the Scandinavian coasts, causing Atlantic water to penetrate deep into the Barents Sea. In contrast, when the NAO index is low, Atlantic water does not penetrate far into the Barents Sea.

Conclusions

Holocene oceanographic changes in the North Atlantic Ocean have been smaller than those of the last glacial period because of the absence of the large terrestrial ice sheets surrounding the basin. Temporal and spatial variations in insolation forcing and deep-water production during the Holocene have led to regional climate oscillations in the North Atlantic region. SST changes of the order of 1–2 °C have been observed throughout the North Atlantic and can be explained by a linear response to mean annual insolation variations (Figure 9). Changes in the thermohaline circulation are becoming better recognized in the high-latitude regions, but remain ambiguous at middle and low latitudes. Deep-water formation and thermohaline circulation changes in the NE North Atlantic appear to be out of phase with similar changes in the western North Atlantic, particularly the Labrador Sea. For example, a reduction in thermohaline circulation in the Barents Sea about 7 ka coincides with an increase in the formation of intermediate water to the west in the Labrador Sea.

In addition to the direct effects of thermohaline circulation and solar variability, inherent variations in the coupled ocean–atmosphere system such as the NAO can cause patterns of North Atlantic change that persist for decades and possibly centuries. Similarly, changes in solar variability may alter the surface wind and ocean dynamics in the North Atlantic, causing repeated occurrences of cold, iceberg-rich Arctic water to penetrate deep into the Nordic and Labrador seas. These oscillations underscore the complex dynamics that is the North Atlantic climate system.

This article is a revision of the previous edition article by A. Koutavas, volume 3, pp. 1847–1855, © 2007, Elsevier B.V.

Introduction

The North Pacific Ocean hosts the largest warm pool, the lowest surface salinities of a major ocean basin, and the oldest deep waters in the world's oceans (Tomczak and Godfrey, 1994). Unlike the Atlantic Ocean, where a vigorous thermohaline circulation exists, the low surface salinity of the North Pacific inhibits deepwater formation at high latitudes, and limits poleward heat transport. In the absence of major rivers draining to the North Pacific, the source of the low surface salinity veneer can be traced in part to the heavy rainfall of the Intertropical Convergence Zone (ITCZ). Today, the ITCZ is located north of the equator most of the year (Waliser and Gautier, 1993), though the evidence that the ITCZ might have occurred in a southerly position during the last glacial period is not strong (McGee et al., 2007). As a consequence of the present northerly location of the ITCZ, and heavy precipitation in the Panama Basin (e.g., Poveda et al., 2006) and the Indonesian Archipelago (e.g., Dai, 2006), a belt of low surface salinity forms in the tropical North Pacific at $\sim 10^\circ\text{N}$, which is advected west via the North equatorial current, and then north via the Kuroshio Current, thus contributing to surface stratification at high latitudes, which prevents deepwater formation and ventilation of the deep ocean (e.g., Tomczak and Godfrey, 1994). The ultimate source of precipitation in the tropical North Pacific resides in the export of moisture from the tropical Atlantic by the northeast trade winds over the isthmus of Central America, which controls the global thermohaline circulation of the ocean (e.g., Zucker and Broecker, 1992).

Therefore, when reconstructing the salinity structure and its modes of variability in the North Pacific, the dynamics of the ITCZ and its sensitivity to latitudinal shifts through time should be considered. For example, a more symmetric distribution of rainfall around the equator should tend to increase North Pacific surface salinity and the production of North Pacific Intermediate Water (NPIW) in the northwest Pacific (NWP) (Koutavas, 2004; Tomczak and Godfrey, 1994).

Increasing sea surface temperature (SST) trends on the order of $0.34\text{--}1.8^\circ\text{C}$, which are opposite to those of the North Atlantic, have been documented in the North Pacific for the past 7 ka. A seesaw pattern possibly responds to inter-oceanic teleconnections driven by the heat budget in the tropics (Kim et al., 2004). By contrast, a decreasing trend in SST has been documented for the same time interval in the Indo-Pacific warm pool (IPWP; e.g., Stott et al., 2004).

Even though the ITCZ is closely linked to the dynamics of the El Niño/Southern Oscillation (ENSO) phenomenon, which exerts a major influence on the North Pacific and global climate, the former has an important paleoceanographic effect due to its strong seasonal dynamics (e.g., Leduc et al., 2009). The zonal SST gradient along the equatorial Pacific Ocean is responsible for the state of the ENSO system, that is, a reduced

zonal SST gradient between the IPWP and the eastern equatorial Pacific (EEP) is typical of the El Niño phase as compared to a strong SST gradient typical of the La Niña phase. Therefore, when these zonal SST gradients persist over centuries to millennia, ENSO-like states result. In addition to this simplistic model, however, other modes of operation of the ENSO system should be considered. This is the case of the Modoki or Central Pacific El Niño (Ashok et al., 2007; Yu and Kim, 2010), which might explain some 'odd' paleoceanographic patterns. The yearly evolution of these Central Pacific events can result in either warming or cooling of the northeastern or eastern Pacific, depending on the thermocline depth at the onset of each event (Ashok et al., 2007).

The ENSO system appears to have experienced significant variability during the Holocene, with evidence suggesting its progressive strengthening of variance from the early-middle to the late Holocene (e.g., Cane, 2005; Clement et al., 2000; Conroy et al., 2008; Gagan et al., 2004; Moy et al., 2002; Rodbell et al., 1999; Sandweiss et al., 2001). Therefore, given the close coupling between ENSO and the ITCZ, and their sensitivity to equatorial winds, the reconstruction of their dynamics during the Holocene needs to be examined together (Koutavas, 2004).

In this article, which updates Koutavas (2004), postglacial and in particular Holocene paleoceanographic records are synthesized, looking for evidence of the relationship between tropical and extratropical processes linking ENSO and the Pacific decadal oscillation (PDO), the ITCZ, and the NPIW, and their influence on North Pacific climate variability. A detailed discussion of the deglaciation interval can be found in Kiefer and Kienast (2005). The present revision follows the North Pacific gyre (Figure 1), beginning in the EEP, the core of the atmospheric moisture transfer between the Caribbean and the Pacific Ocean. Then it follows the path of the cold tongue to the IPWP, the NWP, that is, the Kuroshio Current, and the Subarctic gyre, to return to the tropical Pacific via the northeastern Pacific (NEP) along the California Current.

Paleoceanographic Records from the Equatorial Pacific Ocean: The EEP and the Cold Tongue

Moisture transfer from the Caribbean to the EEP is enhanced during the boreal summer when the ITCZ is in the north (e.g., Leduc et al., 2007; Liu and Tang, 2005; Xie et al., 2008). Therefore, insights can be gained into the dynamics of this major climate feedback mechanism by reconstructing the former position of the ITCZ in the EEP. On the other hand, by comparing Pacific zonal SST gradients, it is possible to reconstruct the dynamics of the ENSO system. This is the case of the comparison between Holocene Mg/Ca SST reconstructions in planktonic Foraminifera from the EEP (Koutavas et al., 2002)

Figure 1 Map of the North Pacific, indicating major sea surface circulation patterns, and the location of records discussed in the text. Broad localities are indicated by gray rectangles, whereas sedimentary sites are indicated by dots: (1) the eastern equatorial Pacific (EEP; e.g., Koutavas et al., 2006; Leduc et al., 2009), (2) the central Pacific (Anderson et al., 2006; McGee et al., 2007), (3) the Indo-Pacific warm pool (IPWP, e.g., Griffiths et al., 2009; Beaufort et al., 2010), (4) the South China Sea (e.g., Huang et al., 2011; Tian et al., 2010), (5) the Okinawa Trough (e.g., Morimoto et al., 2007; Sun et al., 2005), (6) the Kuroshio, Central Japan (e.g., Sawada and Handa, 1998), (7) the Sea of Okhotsk (e.g., Seki et al., 2004), (8) the Bering Sea (Gorbarenko et al., 2010), (9) the Gulf of Alaska (e.g., Barron et al., 2009), (10) northern California (e.g., Barron et al., 2003), (11) Santa Barbara Basin (e.g., Friddell et al., 2003; Roark et al., 2003), (12) southern California (e.g., Barron et al., 2005; Marchitto et al., 2010), and (13) Hawaii (Uchikawa et al., 2010). Laguna Pallcacocha (Moy et al., 2002), the Dongge and Hulu Caves (China, Yuan et al., 2004; Wang et al., 2005) and the Cariaco Basin (southern Caribbean, Haug et al., 2001) are also indicated.

and the IPWP (Figure 2(a); Stott et al., 2004), which suggests that the two regions followed distinct SST trends (Koutavas, 2004; Koutavas et al., 2006). In the early and middle Holocene (10–4 ka), the warm pool and the cold tongue were warmer and cooler by $\sim 0.5^\circ\text{C}$, respectively. As a result, the zonal SST gradient was higher by about 1°C , suggesting a large-scale circulation pattern akin to a La Niña-like state, and a northward shift of the ITCZ (Koutavas et al., 2006). A northward ITCZ location has also been suggested for the Atlantic, based on evidence from the Cariaco Basin, where elevated concentrations of terrigenous titanium in Ocean Drilling Program (ODP) site 1002 occur (Figure 2(b); Haug et al., 2001).

It has been suggested that enhanced insolation in the mid-Holocene (e.g., Berger and Loutre, 1991; Liu et al., 2003) would have made boreal and equatorial summers warmer than present, which in turn would have resulted in a stronger zonal SST gradient across the tropical Pacific, leading to stronger easterly winds and a cooler EEP (Conroy et al., 2008), that is, a stronger Walker circulation and enhanced Bjerknes feedback (Cane, 2005). Other model responses also suggest drastic diminution of interannual ENSO variability (e.g., Clement et al., 2000), which is supported by evidence from coral oxygen isotopes ($\delta^{18}\text{O}$) and laminated sediments from Laguna Pallcacocha, Ecuador (Moy et al., 2002) and El Junco Crater Lake in the Galapagos (Conroy et al., 2008). These lacustrine records

offer unique and continuous records of ENSO variability for the last ~ 12 ka (Figure 2(c); Conroy et al., 2008; Moy et al., 2002). However, there are some conspicuous differences between the Pallcacocha and El Junco records for the early-middle Holocene, which suggests a more complex behavior of the La Niña-like state for the EEP region, perhaps related to unexplored dynamics of the Central Pacific El Niño phenomenon in the past.

The interpreted increase in variance of the ENSO system in the Pallcacocha record during the late Holocene (Moy et al., 2002) follows the general trend of the southward migration of the ITCZ in the Cariaco record (Figures 2(a) and 2(b); Haug et al., 2001). This trend has been interpreted to be driven by declining northern summer insolation, which in turn introduced enhanced air–sea interactions and westerly wind anomalies that triggered an El Niño-like period characterized by more intense/frequent episodes (Koutavas, 2004).

A complementary line of evidence for ENSO dynamics is provided by paleoproductivity records in the EEP. This is the case of enhanced opal burial during deglaciation which was apparently due to ‘silicic acid leakage’ advected from the Southern Ocean at a time of Fe limitation, thus favoring diatom blooms (Dubois et al., 2010). This silica excess increased export production, which in turn would have led to higher oxygen demand and denitrification within the oxygen

Figure 2 Comparisons between postglacial paleoclimate records from the tropical Pacific Ocean: (a) Mg/Ca SSTs from western equatorial Pacific sites MD98-2176 (red; [Stott et al., 2004](#)) and from eastern equatorial Pacific sites V21-30 (blue; [Koutavas et al., 2006](#)); (b) titanium (%) in ODP site 1002 from the Cariaco Basin (southern Caribbean, [Haug et al., 2001](#)); and (c) ENSO frequency inferred from color analysis of sediments from the Equadorian Laguna Pallcacocha (blue; [Moy et al., 2002](#)) and silt (%) from the Galapagos Is., Laguna El Junco (red; [Conroy et al., 2008](#)).

minimum zone in the EEP and the NEP ([Martínez and Robinson, 2010](#); [Robinson et al., 2009](#)). The supply of nutrients was advected from the sub-Antarctic mode water, via the equatorial undercurrent ([Hayes et al., 2011](#); [Peña et al., 2010](#)). Therefore, the increase in productivity is suggestive of enhanced upwelling ([Kienast et al., 2006](#)) under a La Niña-like scenario ([Peña et al., 2008](#)). Other proxy evidence from various records from the EEP support this increase in productivity during deglaciation and the early Holocene (e.g., [Kienast et al., 2007](#); [Martínez et al., 2006](#); [Warnock et al., 2007](#)).

By applying the ^{230}Th normalization technique, [Anderson et al. \(2006\)](#) derived new records of dust flux through the equator along 140°W and found a positive correlation with global ice volume for the past 300 ka. Minimum fluxes of continental mineral aerosol during glacial intervals exceeded those of interglacial maxima by about a factor of 2, similar to changes found elsewhere at low and mid-latitudes. [McGee et al. \(2007\)](#) studied a north–south transect through the equator along 110°W and suggested that during the Holocene the ITCZ has acted as a more effective barrier against interhemispheric dust transport, and that dust fluxes are 25–100% lower than during the last glacial interval. Whether or not this is due to weaker convection or the mean location of the ITCZ remains to be tested.

Paleoceanographic Records from the IPWP, the Kuroshio Current, and the Subarctic Gyre

Accepting a La Niña-like scenario in the early–middle Holocene, presumably sea surface salinities (SSS) in the northern tropical Pacific must have been lower than at present due to persistent rainfall north of the equator ([Koutavas, 2004](#)). This is supported by SSS reconstructions from the IPWP which suggest that SSS might have been somewhat greater during the early Holocene (e.g., [Griffiths et al., 2009](#); [Stott et al., 2004](#)). This scenario seems at odds with $\delta^{15}\text{N}$ data from a set of cores off Mindanao (6.4°N ; 126.4°E) which suggest that the thermocline was shallow during the early Holocene ([Kienast et al., 2008](#)).

In addition to these paleoceanographic inferences, the reconstruction of monsoon dynamics provides some insights into rainfall patterns, leading to a better understanding of salinity patterns in the region. Monsoon dynamics have been reconstructed from paleoceanographic records, and $\delta^{18}\text{O}$ measurements in stalagmites and coral calcite. Being part of the same system, two monsoon regimes are recognized in the western Pacific. The Australian–Indonesian monsoon (AIM) and the East Asian monsoon (EAM) are synchronous in their

opposing hemispheres, that is, while there are dry (wet) conditions at AIM during Boreal winter (summer), there are wet (dry) conditions at the EAM. The ITCZ is located in a southerly location during Boreal winter, and a northerly location in summer.

Griffiths et al. (2009) studied the Liang Luar stalagmite $\delta^{18}\text{O}$ record (Flores Island, Indonesia, Figure 3(a)) and argued in favor of a steady increase in Australian–Indonesian summer monsoon (AISM) during the early Holocene. They argue that precipitation, which increases during austral summer, does not appear to show a direct relation to insolation, but was apparently controlled by sea-level rise. In contrast, the coccolith and pollen record of core MD98-2175 (5°S–133.45°E; eastern Banda Sea) suggest that the AISM rainfall follows the pattern of glacial–interglacial dynamics, whereas the AIWM proxies (primary production and length of the dry season) are strongly influenced by precessional cycles, that is, low-latitude insolation during the austral winter (Beaufort et al., 2010). Furthermore, the synchrony of the AIM with other regional monsoon systems and ENSO at precession timescales suggests a common climatic forcing and highlights the role of the tropics on global climate (Beaufort et al., 2010).

As for the latest Holocene, geochemical data from a sediment core in the shallow silled and intermittently dysoxic Kau

Bay in Halmahera (Indonesia, 1°N; 127.5°E) were used to reconstruct century-scale variability in climate and basin ventilation within the IPWP (Langton et al., 2008). Downcore variations in bulk sedimentary $\delta^{15}\text{N}$ were attributed to changes in oceanographic conditions related to fluctuations in the ENSO system, that is, a century-long increase in El Niño activity beginning ca. 1.7 ka, with peaks in El Niño activity ca. 1.5, 1.15, and 0.7 ka. Kau Bay results suggest that there was diminished ENSO amplitude, or a departure from El Niño-like conditions during the Medieval Warm Period, and a distinctive, but steady decrease of El Niño activity during and after the Little Ice Age (Langton et al., 2008). These are interesting results that appear to be the opposite of those for the entire Holocene at the IPWP, that is, El Niño during warm periods, and vice versa. More data will lead to a better understanding of these high-frequency fluctuations through the Holocene.

Unlike the Liang Luar stalagmite record, the $\delta^{18}\text{O}$ record of planktonic Foraminifera in core G5-2-056P (3.58°S; 132.18°E, Seram Trough, eastern Indonesia, Brijker et al., 2007) suggests a steady decline in SST and SSS from the early to the mid-Holocene (10.6–6 ka). Climate conditions were ‘stable’ during the early Holocene compared to the mid–late Holocene when El Niño-like conditions apparently arose; the transition occurred at 6–4.5 ka (Brijker et al., 2007), in agreement with

Figure 3 Comparisons between postglacial paleoclimate records from the northern Pacific. (a) $\delta^{18}\text{O}$ of the Indonesian Liang Luar stalagmite (Griffiths et al., 2009), (b) $\delta^{18}\text{O}$ of the Chinese Dongge Cave stalagmite (Yuan et al., 2004), and (c) Mg/Ca SST record of the Baja California Sur, Soledad Basin (Marchitto et al., 2010).

the EEP, to end in a steady increase from 4 ka onward. A similar pattern was found in core MD01-2378 (13.08° S, 121.79° E, Timor Sea, eastern Indian Ocean; Xu et al., 2008). In both cases, it is argued that orbital configuration might have favored the northward shift of the ITCZ, resulting in intensification of the EAM, weakening of the AISM, and strengthening of southeastern trade winds during the austral summer. The timing and pattern difference between the stalagmite and the sedimentary records accounts for the regional variability, which is typical of the IPWP.

A high-resolution planktonic foraminifer Mg/Ca SST and $\delta^{18}\text{O}$ record of core MD052896 (southern South China Sea, SCS) provides a history of EAM dynamics over the past 23 ka, as indicated by the latitudinal temperature gradient (ΔSST ; Tian et al., 2010). The EAM was stronger during cold periods, including Heinrich 1 (H1, 17.5–14.7 ka) and the Younger Dryas (YD, 12.8–11.7 ka) events. The ΔSST record also indicates that after ~ 8.5 ka, the EAM strengthened relative to deglaciation, reaching similar levels to those of the last glacial period. By comparing the SCS ΔSST with stalagmite $\delta^{18}\text{O}$ records, it is suggested that both the East Asian summer monsoon (EASM) and East Asian winter monsoon (EAWM) strengthened from the last glacial to the Holocene, and that the migration of the ITCZ most probably has not been the only cause of EAM variability (Tian et al., 2010).

Reconstructed alkenone unsaturation index (U^{k}_{37}) SSTs from the SCS suggest warming trends through the Holocene (e.g., Kiefer and Kienast, 2005; Kim et al., 2004; Wang et al., 1999) in comparison with cooling trends, reconstructed with the foraminiferal Mg/Ca proxy, in the Philippine–Indonesian Seas region (Stott et al., 2004). The difference might be real or due to biases imposed by the various proxies used (e.g., due to seasonal, ecological, or diagenetic effects; Koutavas, 2004), or due to effects of the EAM and AIM dynamics. The divergence has also been observed in SSS trends, as shown by a high-resolution record from site 17940 (20° N; northern SCS) that suggests a progressive increase in salinity through the Holocene, consistent with the decreasing strength of the EASM (Wang et al., 1999). Moreover, power spectrum analysis of this salinity record reveals frequencies consistent with a possible solar forcing of monsoonal rainfall. Solar forcing of the EAM has also been proposed for the Dongge, China $\delta^{18}\text{O}$ stalagmite record on the basis of high-frequency precipitation changes (Wang et al., 2005). Salinity reconstructions from the Indonesian Seas, unlike the SCS, suggest freshening through the Holocene (Stott et al., 2004).

The connection between EAM dynamics and the cold tongue, based on U^{k}_{37} SSTs estimates, suggests that the zonal SST gradient in the southern SCS reflects the temporal dynamics of the winter ‘cold tongue’ off southern Vietnam and variations in the EAM intensity, and that winter ‘cold tongue’ SSTs were lower at H1 and the YD events, resulting in an increased zonal SST gradient in the southern SCS due to a strengthened EAM (Huang et al., 2011). Within dating uncertainties, an intensified EAM during cold stadials was apparently coeval with the shutdown or a reduction in strength of the Atlantic meridional overturning circulation (AMOC). The zonal SCS SST gradient also indicates an enhanced EAM during the early Holocene, which may be induced by postglacial ice-sheet dynamics and a strong seasonal contrast in solar insolation (Huang et al., 2011). In accord to Tian et al. (2010), results

suggest that the EAM was probably modulated by a complex interplay between the AMOC, solar insolation and ice-sheet dynamics on sub-orbital time scales.

Sedimentary geochemical records from subalpine Retreat Lake (24.5° N; 121.44° E; Taiwan) appear to indicate an unstable EAM climate over the past ~ 10.3 ka, with a weak EAM between ~ 10.3 and 8.6 ka, more intense peaks between 8.6 and 7.7 ka, and a gradual decrease in response to summer insolation, heat, and moisture transport (Selvaraj et al., 2007). The total organic carbon record apparently reveals several weak monsoon intervals that correlate to low SSTs in the western tropical Pacific and cold events in the North Atlantic. These weak EAM events at 8.2, 5.4, and 4.5–2.1 ka also appear to correspond to low values of atmospheric methane and periods of reduced AMOC (Selvaraj et al., 2007).

Further north in the NWP, the reconstruction of the EAM strength from the Hulu and Dongge (China) stalagmite $\delta^{18}\text{O}$ records reveals significant variability on millennial and sub-millennial timescales for the last glacial period and the Holocene (e.g., Dykoski et al., 2005; Wang et al., 2005; Yuan et al., 2004; Figure 3(b)). According to the stalagmite records, postglacial EAM strength peaked in the early to mid-Holocene (11.5 to ~ 3.5 ka) and gradually declined through the late Holocene, with a slight increase after 2 ka (Figure 3(b)). As expected, this pattern is opposite to the AISM (Figures 3(a) and 3(b)).

In addition to the apparent consistency of the EAM trend with forcing by Northern Hemisphere summer insolation, abrupt shifts in the $\delta^{18}\text{O}$ signal suggest that threshold effects may be important (Dykoski et al., 2005). An important observation of Dykoski et al. (2005) is that the Holocene EAM centennial- and multidecadal-scale monsoon variability in the Dongge record is significant, although not as large as glacial millennial-scale variability, that is, it is less than half the amplitude. Additionally, they show how this high-frequency variability correlates with the Ti record of the Cariaco Basin (Figure 2(b)), and that there is a strong connection with northern South American hydrological changes related to the dynamics of the ITCZ. Furthermore, Dykoski et al. (2005) found peaks at solar periodicities of 208 and 86 years in a spectral analysis of the $\delta^{18}\text{O}$ record, together with peaks at ENSO frequencies, suggesting that both solar forcing (cf. Emile-Geay et al., 2006) and changes in oceanic and atmospheric circulation patterns might have been important in controlling Holocene monsoon climate.

The Mg/Ca and $\delta^{18}\text{O}$ signals of *Globigerinoides ruber* SST and SSS reconstructions in core A7 (28° N) from the Okinawa Trough were used to explore the link between EAM strength and subtropical SSTs for the last 18 ka (Sun et al., 2005). Results show that even though there are common features in variability between monsoon strength and SST during the deglaciation interval, Holocene SSTs at A7 site appear to be more stable than the strength of the EAM and apparently SSS only increased slightly in the early–middle Holocene, which contrasts with the notion of a stronger EAM (Koutavas, 2004; Sun et al., 2005). Sun et al.’s (2005) interpretation is that there was a decoupling between sea surface conditions and the EAM in the Okinawa Trough, in response to an inland shift of monsoonal rainfall, resulting in a net precipitation decrease in the ocean during the early–middle Holocene. This

interpretation seems to be supported by (1) a correlation between an increased freshening and high productivity with high monsoon intensity in the East China Sea during interstadials including the Holocene (Chang et al., 2009), and (2) an SST and SSS reconstruction from two fossil corals from Kikai Island (28.33°N; 130.03°E), which show that at ~6.2 ka, SSTs were similar to today in summer and winter, whereas SSSs were higher both in summer (+0.5‰, +1.1 psu) and in winter (+0.2‰, +0.6 psu) than modern values (Morimoto et al., 2007).

The Kuroshio Current transports large amounts of heat from the IPWP to high latitudes. Therefore, the reconstruction of the Kuroshio strength, pathway, and volume are important paleoceanographic aspects. The Kuroshio Current was probably confined east of its present position during the last glacial interval (Ujiie et al., 2003), then it reentered the Okinawa Trough at ~7.3 ka and subsequently experienced substantial millennial-scale fluctuations, possibly related to Northern Hemisphere climate shifts. This is suggested by the abundance of *Pulleniatina obliquiloculata*, a proxy of the Kuroshio Current, and foraminiferal SST reconstructions (Jian et al., 2000). The timing of this reentry in the Okinawa Trough is supported by a reconstruction of the north–south SST gradient from a set of cores off central Japan; results suggest that the Kuroshio Current reached maximum strength at ~7 ka and progressively weakened toward the present day (Sawada and Handa, 1998). Jian et al. (2000) attributed the mid-Holocene peak in transport to an intensification of the subtropical gyre and the North equatorial current, which was driven by an insolation maximum in summer. The ENSO state may also have influenced the variability of the Kuroshio Current during the Holocene, that is, through cold tongue dynamics. Because the Kuroshio Current weakens today during El Niño events, by analogy, the proposed increase in ENSO frequency in the late Holocene (Moy et al., 2002) may have contributed to its reduction (Koutavas, 2004). Furthermore, the conspicuous decrease in abundance of *P. obliquiloculata* in cores from the Kuroshio source region and the SCS between ~4.5 and 2.7 ka, which suggests a marked decrease in the influence of the Kuroshio and associated climatic cooling, also suggests a link to the EAM (Jian et al., 2000). This interpretation appears consistent with a significant decrease in EAM strength at about the same time, as revealed in the stalagmite $\delta^{18}\text{O}$ records from Dongge Cave in China (Figure 3(b)). By contrast, Ujiie et al. (2003) suggest that the *P. obliquiloculata* event might not reflect sea surface cooling, but (a) a regional change of the subsurface structure of the Kuroshio, or (b) reduced primary productivity in the Kuroshio source region due to enhanced activity of the ENSO system.

Further support for a reduced Kuroshio Current after the middle Holocene is provided by Sagawa et al. (2011), who reconstruct variations in SST and vertical thermal structure in the western subtropical North Pacific, based on planktonic $\delta^{18}\text{O}$ and Mg/Ca records from core ASM-5PC (28.38°N; 132.75°E) for the last 30 ka, and conclude that when the EAWM strengthens, water convection increases and intermediate depth temperatures decrease. Therefore, by the mid-Holocene, when intermediate temperatures were warmer, the EAWM strength was weak. This reconstruction agrees with the Hulu and Dongge stalagmite $\delta^{18}\text{O}$ records.

Core PC6 (40°N, 143°E, off Sanriku, Japan), retrieved under the present-day Oyashio front in the southern Subarctic gyre, provided a record of biological production and U^{37}_{37} SST for the last 27 ka (Minoshima et al., 2007). Biogenic opal content was low until the early Holocene, and rapidly increased at 6 ka. Low biological production in the mixed layer resulted from nutrient depletion, especially silica, during the deglaciation (15–9.5 ka) in comparison to the late Holocene (6 ka – present) when biological productivity increased. Nutrients were probably supplied from deeper levels by eddies rather than by the Oyashio Current. Despite limitations in chronology, these results seem to reveal an opposite trend to the Kuroshio region, that is, a weakening of the Kuroshio Current was accompanied by a strengthening of the Oyashio Current after the middle Holocene (Minoshima et al., 2007).

From a set of cores (51°N, 152°E; Sea of Okhotsk), productivity in the source region of the NPIW was found to change from a coccolithophorid- to a diatom-dominated system in the mid-Holocene, which might have resulted from a salinity-induced breakdown of surface stratification, allowing the upwelling of silica-rich subsurface water (Seki et al., 2004). The hypothesis here is that the increase in salinity in the late Holocene may involve a decrease in East Asian continental rainfall and a broad reorganization of the EAM (Seki et al., 2004).

In a more oceanic setting, core MD01-2416 (51°N, 168°E) provides a centennial-scale multiproxy record of subarctic North Pacific SST, SSS, and productivity for the Holocene (Sarnthein et al., 2004). Results reveal a gradual decrease in SST by 3–5°C from 11.1 to 4.2 ka and a stepwise long-term decrease in SSS by 2–3 psu. early Holocene SSSs were as high as in the modern subtropical Pacific. The steep halocline and stratification that characterizes present-day subarctic North Pacific waters is the product of mid-Holocene environmental change. High SSSs matched a productivity maximum of biogenic opal from the Bølling interstadial interval to the early Holocene (Sarnthein et al., 2004).

Finally, at the northern edge of the NWP, the $\delta^{18}\text{O}$ benthic Foraminifera of cores GC-11 (53.5°N, 178.85°E) and G-13 (53.68°N, 178.72°E, Bering Sea) provide a record of the last glacial to the mid-Holocene changes in global deepwater $\delta^{18}\text{O}$ and a rise in deepwater temperature from 1.2°C to 1.6°C between 8.5 and 6.5 ka. The subsequent environmental changes in the late Holocene led to modern-day conditions, characterized by a strong stratification and reduced deepwater ventilation (Gorbarenko et al., 2010).

Paleoceanographic Records from the NEP

High-resolution records of diatoms, silicoflagellates, and geochemistry (U and Mo) from the Gulf of Alaska show a decrease in productivity during the YD, which was followed by an increase during the early Holocene, a pattern that is analogous to several locations on the California margin. The increase in abundance of upwelling-related diatoms and Mo suggest that low oxygen bottom conditions were more intense between ~6.5 and 2.8 ka (Barron et al., 2009). In a similar approach, diatoms, silicoflagellates, and biogenic silica were analyzed from two cores from the Effingham Inlet, British

Columbia, where conditions of relatively high productivity were found between 4.85 and 4 ka, followed by a transition to the modern, and variable, ocean–climate regime since 2.8 ka, except for a brief period of warmer and drier conditions and possibly increased coastal upwelling offshore ca. 1.45–1.05 ka (Hay et al., 2007). Even though there are some common features between the Alaskan and British Columbia records, such as the 2.8 ka event, other differences possibly reveal regional variability. By contrast, the U^{k}_{37} SST reconstruction from core JT96-06 PC (49° N, Canadian margin) exhibits a strong YD cooling, followed by a warm peak in the early Holocene, cooling in the middle Holocene and a slight return to warmer SSTs in the late Holocene (Kienast and McKay, 2001). This SST pattern is similar to ODP 1019 from northern California (Barron et al., 2003), therefore suggesting a broad pattern of climate variability for the NEP.

The California Margin, and in particular the Santa Barbara basin (SBB), has been the focus of high-resolution paleoceanographic studies for the late Quaternary due to the influence of the California Current and the restricted bathymetry of the basins, which make sedimentary records sensitive to surface (upwelling) and bottom (oxygen) water properties, which in turn respond to millennial- and submillennial-scale climate variations (e.g., Behl and Kennett, 1996; Hendy and Kennett, 1999; Kennett and Ingram, 1995).

The study of diatoms, pollen census data, and U^{k}_{37} in ODP site 1019 (42° N, off northern California) revealed a strong cooling during the YD, warming in the early Holocene (11.5–8.5 ka), cooling by 1–2 °C in the middle Holocene (8.5–3.5 ka), and then returning to present-day values (Barron et al., 2003). The mid-Holocene cool interval is associated with opposite variations in the abundance of diatoms, that is, the decrease of the gyre species *Pseudoemotia doliolus* at the expense of the increase of the upwelling species *Thalassionema nitzschioides*, suggesting that intensification in upwelling was at least partly the cause of cooler temperatures (Barron et al., 2003). This interpretation is in accord with the interpretations of Gardner et al. (1997) and Barron and Burky (2007), who concluded that increases in biogenic mass accumulation rates along the California margin resulted from enhanced productivity due to stronger upwelling during the mid-Holocene. This would mean a stronger subtropical gyre in a La Niña-like scenario.

Pollen, geochemical (organic carbon, carbonate, and biogenic silica), and U^{k}_{37} analyses of ODP site 1018 (36.98° N, 123.28° W) provide evidence of wet conditions associated with a rapid rise in SST during deglaciation (Lyle et al., 2010). While SST gradients along the California margin suggest the weakening of the California Current and coastal upwelling, they proposed that wet periods in central California are connected to the tropical Pacific by the northward movement of temperate Pacific water into the Alaska gyre. The wettest period in the SBB peaked at 16 ka, preceding the wet peak in central and northern California by 4 ka (Lyle et al., 2010).

Bottom-water oxygenation levels at ODP site 893 (500 m sill depth; 34° N; California margin) were reconstructed using a bioturbation index, where laminated sediments are indicative of low oxygen conditions and warm climate intervals (Behl and Kennett, 1996). As for the Holocene period, coccolith assemblages and biogenic burial rates at ODP site 893 show that bioturbation varied with oxygen changes at the sea floor,

compared to the lamination that varied with lithogenic particles, thus favoring the interpretation that deepwater ventilation (Nederbragt et al., 2008) and the strength of the NPIW must have been important (Koutavas, 2004). In fact, the northern origin of intermediate water masses on postglacial times is supported by carbon isotope ($\delta^{13}C$) measurements on *Cibicides wuellerstorfi* in the EEP core MD02-2529 (8.2° N; 84.12° W; Leduc et al., 2010). Furthermore, in support of the NPIW hypothesis, Roark et al. (2003) measured the radiocarbon age to document the difference between benthic and planktonic Foraminifera in the SBB, and found that there is some degree of consistency between it and the Holocene bioturbation index, a connection which is probably related to the strength or source of NPIW and the AMOC. Of interest is the significant increase in the benthic–planktonic age difference at ~2 ka BP, which has persisted to the present day. This change is close to the one reported for Effingham Inlet (British Columbia, Hay et al., 2007) and other sites in the EEP (e.g., El Junco, Galapagos Is., Conroy et al., 2008). This change implies a shift to weaker NPIW ventilation in the latest Holocene, which coincides with the presence of increased laminations in the sediments (Roark et al., 2003).

Measurements of $\delta^{18}O$ in the planktonic Foraminifera *Globigerina bulloides* (a surface dweller) and *Neogloboquadrina pachyderma* (a thermocline dweller) in core AII-125 JPC-76 (34° N, SBB), and their isotopic difference ($\Delta\delta^{18}O$), were used to interpret the degree of surface stratification in relation to ENSO system dynamics, that is, positive ENSO anomalies led to increased stratification in the SBB, and vice versa (Friddell et al., 2003). Their results show a somewhat reduced isotopic difference (reduced stratification) between 9 and 5.5 ka, implying a decline in ENSO variability, that is, a La Niña-like early–middle Holocene state, documented in the tropical Pacific (Figure 2(a)). Conversely, a larger isotopic gradient (increased stratification) and enhanced decadal-scale surface variability between 5.5 and 3.5 ka may imply the onset of a strong ENSO system. In addition to the influence of the ENSO system on the SBB, Friddell et al. (2003) conclude that the variability of the PDO might significantly help explain the apparent weakening of the ENSO system by ~3.5 ka. By contrast, Barron and Burky (2007) point to enhanced tropical variability, which is not restricted to the Pacific, but has been documented in the Cariaco basin (Haug et al., 2001).

Multiscale dynamic interactions affecting the California Current were explored by Diffenbaugh and Ashfaq (2007), who used a Regional Climate Model (RegCM3) and suggested that mid-Holocene insolation might have caused systematic changes in wind forcing of the current, suppressing and enhancing wind stress in spring, and summer–autumn, respectively. Their climate model simulations for the mid-Holocene are supported by proxy-inferred cooler-than-present SSTs as well as by high $\delta^{15}N$ values in the northern and southern California Current system, respectively (Diffenbaugh and Ashfaq, 2007).

Diatom and silicoflagellate data from GGC55, JPC56, and DSDP 480 cores in the Guaymas Basin (Gulf of California) show a pattern of reduced productivity, which suggests cool SSTs in the early–middle Holocene until ~6 ka when productivity increased (Barron et al., 2005). This pattern apparently

parallels the evolution of the ENSO system through the Holocene (Barron et al., 2005).

Further south, and analogous to the SST pattern of the EEP and numerical model simulations of orbital forcing, the Mg/Ca SST record of the Soledad Basin (25.2° N; 112.7° W; Baja California, Mexico) shows cool values during the early–middle Holocene (Figure 3(c); Marchitto et al., 2010). In the early Holocene, millennial-scale fluctuations in SST correlate with cosmogenic nuclide (proxies of solar variability), with inferred solar minima corresponding to El Niño-like conditions, in apparent agreement with the theoretical ‘ocean dynamical thermostat’ response of ENSO to exogenous radiative forcing. The results of Marchitto et al. (2010) are in agreement with a previous interpretation of the $\delta^{18}\text{O}$ record of a stalagmite from the Pink Panther Cave (New Mexico) which was used to reconstruct the dynamics of the North American monsoon (Asmerom et al., 2007).

Through the study of core MV-99, GC-31 (23.47° N, 111.60° W; Magdalena margin, Baja California, Mexico), Ortiz et al. (2004) linked changes in bottom-water oxygen content to millennial-scale climate changes, as recorded by the $\delta^{18}\text{O}$ composition of Greenland ice, and suggested that this teleconnection predominantly resulted from changes in marine productivity, rather than changes in ventilation of the North Pacific. In accord with other studies, the interpretation is that the deepening of the thermocline and weakening of the nutricline during El Niño events reduce productivity (e.g., Barron et al., 2005).

The postglacial paleoceanography of the NEP is synthesized by Barron and Anderson (2011), who indicate that there were (1) La Niña-like or more negative PDO-like conditions, during the middle Holocene (8–4 ka), and (2) a climate transition between ~4.2 and 3 ka, leading to modern ENSO variability. More detailed interpretations, in relation to modern-day conditions, suggest that during the middle Holocene, the Aleutian Low was weaker during the winter and/or located to the west, while the North Pacific High was stronger during the summer and located to the north. Coastal upwelling off California was more vigorous during the summer and fall but suppressed during the spring, whereas Oregon and California SSTs were cooler compared to the SBB. late Holocene records indicate a more variable, El Niño-like and more positive, PDO-like system, with the Aleutian Low more intense during the winter and/or located to the east, and the North Pacific High weaker and/or displaced to the south. Coastal upwelling off California intensified during the spring but decreased during the fall. Oregon and California SSTs became warmer, recording the shoreward migration of the subtropical gyre during the fall, while spring upwelling increased in the SBB. The high-resolution proxy records indicate enhanced ENSO and PDO variability after 4 ka off southern California, 3.4 ka off northern California, and by 2 ka in southwestern Yukon. A progressively northward migration of the ENSO teleconnection during the late Holocene is proposed. This 2-ka time difference contrasts with the 4-ka differential reported for deglaciation by Lyle et al. (2010), as indicated before.

For the center of the North Pacific gyre, the carbon isotope record from Ordy Pond (21.3° N, 158.05° W, Oahu Is. Hawaii) provides evidence for an increasing C_4 trend with respect to C_3 plants along the Holocene, thus suggesting that the central

subtropical Pacific became drier, possibly due to a winter warming of the cold tongue in the EEP which was orbitally forced in an analogous way to the modern ENSO phenomenon (Uchikawa et al., 2010). Except for two major peaks at 5 and 0.5 ka, the trend seems coherent with SST reconstructions, and cold tongue weakening in the EEP (e.g., Kienast et al., 2006; Koutavas and Sachs, 2008; Leduc et al., 2007).

The ENSO System at Millennial Timescales

Besides the proxy recognition of ENSO-like states during the Holocene, there has been a search for their forcing mechanisms. This is the case of the ~1 or ~1.5 ka periodicity in SST variability at millennial timescales in the North Pacific during the Holocene, which is attributed to solar and orbital forcing that is still a matter of debate (e.g., Ditlevsen et al., 2007; Isono et al., 2009; Marchitto et al., 2010). One proposition is that tropical convection, controlled by the meridional location of the ITCZ, controls the emissions of the greenhouse gases CH_4 and N_2O and acts as a global climate amplifier (Ivanochko et al., 2005). In accord with proxy evidence, model results based on radiocarbon production suggest that there was an increase in ENSO variability and that it may have acted as a mediator between the Sun and the Earth’s climate (Emile-Geay et al., 2006). The increase in ENSO variability, reduced during the mid-Holocene, is evident from the spectral analysis of 124 proxy time series (Wirtz et al., 2010).

To mention one model, Lorenz et al. (2006) used a coupled atmosphere–ocean circulation model to explore insolation forcing on U^{k}_{37} global SST trends over the last 7 ka. They found that the extratropics cooled while the tropics warmed during the middle to late Holocene, in response to seasonally opposite insolation changes, and that climate mode changes similar to the Arctic/North Atlantic Oscillation are superimposed on the prevalent pattern. Furthermore, nonlinear changes in the seasonal cycle of insolation appear to be a key factor in the evolution of Holocene SSTs (Lorenz et al., 2006). An important observation of this experiment is that the timing of phytoplankton production is controlled not only by summer insolation in high latitudes, but also by the shift in the maximum insolation in low latitudes. This might explain the timing differences along the California margin described earlier. The difficulties reproducing accurately the mid-Holocene La Niña-like state are summarized and discussed by Chiang (2009).

Summary

From this compilation, it is apparent that the influence of the ENSO system extends all over the North Pacific during the Holocene, and that for centuries to thousands of years, El Niño-like and La Niña-like conditions can become the dominant state. Apart from a general pattern where the Kuroshio Current is weakened and the California Current is strengthened during El Niño- and La Niña-like states, respectively, there are significant regional differences. These are imposed by the interaction between the EAM and AIM in the IPWP and the northwest Pacific, and the PDO and the NPIW in the

northeast Pacific. Of major interest is the recognition that the AISM is not only controlled by solar insolation, but also by sea-level change. Similarly, more robust evidence is building for teleconnections between the EAM, the California Current, and the AMOC, modulated by insolation and ice-sheet dynamics on suborbital time scales. The general paleoceanographic picture for the North Pacific in the Holocene is one of a La Niña-like (negative PDO) state during the early–middle Holocene to one of El Niño-like (positive PDO) state during the late Holocene. Therefore, the ITCZ changed from a northern to a southern location from the middle Holocene to the late Holocene. This might have reduced the strength of the Kuroshio and California Currents.

Postglacial South Pacific

Introduction

The South Pacific Ocean covers a major part of the Southern Hemisphere (SH) and plays an important role in the global climate system. Nevertheless, postglacial (Holocene) paleoceanographic records from this ocean are scarce because large parts are covered by deep sea basins, often too deep for carbonate preservation and thus not suitable to obtain records with sufficient time control and resolution (Figure 1). Therefore, most available Holocene paleoceanographic data originate from the margins of the surrounding continents where higher terrigenous sediment supply, combined with enhanced biological productivity and preservation, provides a much better potential for studying Holocene paleoenvironmental variability. After briefly discussing the modern oceanographic and climatic background, the main focus of this article concerns postglacial records from the continental margins off South America (Peru and Chile), New Zealand/Australia, and the Antarctic Peninsula (Palmer Deep). The available paleoceanographic data primarily focus on surface ocean records, such as sea surface temperatures (SSTs), paleosalinity, and paleoproductivity estimates. These data are complemented with information on terrestrial paleoclimates, as derived from the marine records. In addition, major forcing mechanisms involved in Holocene paleoenvironmental variability in the South Pacific realm are summarized, and critical issues for future research are identified.

Oceanographic and Climatic Setting

General Ocean Circulation

The South Pacific Ocean is dominated by deep basins, including the Peru and Chile basins in the eastern part, and the large southwest Pacific basin in the west (Figure 1; Tomczak and Godfrey, 2003). These basins are separated from each other by oceanic ridge systems, the most important being the Nazca Ridge and the East Pacific Rise. In the westernmost part of the South Pacific, New Zealand and the Melanesian Islands build the boundary for smaller adjacent basins including the Tasman Sea, the South Fiji Basin, and the Coral Sea. Deep basins are also characteristic of the Pacific sector of the Southern Ocean, south of the Pacific Antarctic Rise and eastwards reaching the Drake Passage and the Antarctic Peninsula (Figure 1).

The most prominent surface circulation feature of the South Pacific is the subtropical gyre (Tomczak and Godfrey, 2003; Figure 2). Its eastern boundary current is the Peru–Chile Current (PCC) system that largely exchanges heat and nutrients between high and low latitudes in the eastern Pacific. The main surface current originates from the northern margin of the Antarctic Circumpolar Current (ACC) that splits at around $\sim 43^\circ\text{S}$ off the coast of western South America into the PCC

flowing northward and the Cape Horn Current turning toward the south (Figure 3; Strub et al., 1998). Northward, the PCC is divided into coastal and oceanic branches through the poleward-flowing Peru–Chile countercurrent (PCCC). The PCC is the most extensive Eastern Boundary Current system in the world, driven by south-easterly winds along the Pacific coast of South America (Strub et al., 1998). The resulting offshore Ekman flow drives perennial upwelling of cool, nutrient-rich waters that support one of the most biologically productive regions in the oceans. At about 5°S , the PCC is deflected offshore, feeding the South Equatorial Current and flowing westward as the equatorial cold tongue between 10°S and 4°N . The western boundary currents of the South Pacific are less well developed (Tomczak and Godfrey, 2003) and consist of the East Australia Current between 18°S and Tasmania and another southward current along the east coast of New Zealand (the East Cape Current; Figure 2) that interrupts the more usual western boundary current formation seen in other oceans. The ACC system south of the subtropical gyre is one of the most important oceanic current systems, as it is the principle route for interocean transport. The ACC separates subtropical and polar water masses through three principal oceanic fronts: the subtropical front, the subantarctic front, and the Antarctic polar front where water mass characteristics change rather abruptly (Tomczak and Godfrey, 2003).

Wind Pattern

Corresponding to the general surface ocean circulation, the large-scale atmospheric circulation of the South Pacific region is comparatively simple (Tomczak and Godfrey, 2003). The subtropics are largely controlled by the semipermanent anticyclone over the southeast Pacific, resulting in moderately strong but very persistent southeast trade winds. South of the high pressure cell, the mid- to high-latitude South Pacific is dominated by extremely intense and prevalent westerly air flow. These strong so-called Southern Westerlies are annually centered around $50\text{--}55^\circ\text{S}$, corresponding to the steepest SST gradients within the ACC. Seasonally, the westerlies are latitudinally more confined and stronger in austral summer. During austral winter, zonal wind strengths are reduced in the center of the westerlies, but the whole wind belt extends further northward where zonal winds are thus enhanced. The westerlies result from the strong thermal gradient and atmospheric pressure difference between cold air masses over Antarctica and the warmer air and water masses in the subtropical regions (Cerveny, 1998).

El Niño Southern Oscillation

The South Pacific is the classical region for studying the impacts and the atmospheric and oceanographic processes of the

Figure 1 Map of the South Pacific showing major bathymetric features and the location of marine sediment cores and other paleoclimate archives discussed in the text.

Figure 2 Map of the South Pacific showing major surface currents (after Tomczak and Godfrey, 2003).

El Niño Southern Oscillation (ENSO) as a major source for global climate variability on interannual timescales. During the positive phase of ENSO (El Niño events) that occurs roughly every 3–7 years, SSTs substantially increase in the eastern equatorial Pacific and the northern part of the PCC system, with important effects on continental rainfall in the subtropics and marine productivity of the Peruvian upwelling area (Tomczak and Godfrey, 2003). At the same time, the southeast Pacific anticyclone weakens and the storm tracks of the Southern Westerlies expand toward the north, resulting in above-average rainfall in mid-latitude Chile (Cerveny, 1998),

showing that the effects of ENSO are not restricted to the tropics/subtropics.

Continental Margin Records

South American Margin off Central and Southern Chile

Compared to other regions of the SH, marine sediments along the continental margin off Chile have been comparatively thoroughly studied after a number of international research cruises during the past 15 years. However, the first paleoenvironmental

Figure 3 Sea surface temperature (SST) records off Chile compared to Antarctic and South American ice core data. Gray bar marks early Holocene maximum warm phase as defined at ODP Site 1233 (Kaiser et al., 2005). (a) Huascarán $\delta^{18}\text{O}$ record as a proxy for temperature changes in tropical South America (Thompson et al., 1995). (b) Opal accumulation rate (AR) record from core GeoB 7112-2 (Mohtadi et al., 2004) as a proxy for marine productivity. Higher values imply enhanced productivity and cooler SSTs. (c) SST record from core GeoB 7139-2 off north-central Chile (Kaiser et al., 2008). (d) SST record from ODP Site 1233 (Kaiser et al., 2005; Lamy et al., 2007). (e) Precipitation reconstruction for central Chile based on hydrological modeling of lake-level data (Jenny et al., 2003). (f) Terrestrial organic carbon AR record of core TM1 as a proxy for precipitation in southernmost Chile (Lamy et al., 2010). (g) δD record from the Taylor Dome ice core as a proxy for western Antarctic temperature (Steig et al., 1998). (h) δD record from the Dome C ice core as a proxy for eastern Antarctic temperature (EPICA Community Members, 2004).

records from the remote southern Chilean Fjord Region have only recently become available (Kilian et al., 2007; Lamy et al., 2010; Sepulveda et al., 2009). Pronounced gradients in oceanographic and climatic features make the Chilean margin particularly suitable for the study of postglacial paleoenvironmental variability at the northern margin of the ACC and the Southern Westerlies.

In terms of postglacial 'long-term' trends, SST records from the Chilean margin suggest an early Holocene maximum warming most clearly depicted at Ocean Drilling Program (ODP) Site 1233 (41° S), where SSTs peak between ~12.5 and 9 ka BP (Kaiser et al., 2005; Lamy et al., 2007; Figure 3(d)). This early Holocene optimum is likewise visible in a low-resolution alkenone SST record off southernmost Chile (MD07-3128; ~53° S; Caniupan et al., 2011) and coincides with warm conditions recorded both in the Eastern Antarctic Dome C (EPICA Community Members, 2004), and the Western Antarctic Taylor Dome ice cores (Steig et al., 1998), where the maximum warming appears to be restricted to a shorter interval, however (Figure 3(g) and 3(h)). An SST record off northern mid-latitude Chile (30° S; Figure 3(c); Kaiser et al., 2008) displays a slightly delayed optimum warming that lasted longer, that is, into the middle Holocene, a pattern that likewise appears in the tropical alpine South American ice core record recovered at the Nevado de Huascarán (Figure 3(a); Thompson et al., 1995). Except for the Dome C record, both Antarctic ice core and the paleoceanographic records display a cooling trend toward the late Holocene (Figure 3). The general temperature pattern during the Holocene is paralleled by opposing trends in continental rainfall between central and southern Chile (Lamy et al., 2010). In central Chile, located at the northern margin of the Southern Westerlies, regional terrestrial records and the terrigenous components in marine records generally suggest drier conditions during the early and middle Holocene and increased precipitation during the late Holocene (Figure 3(e); Jenny et al., 2003; Lamy et al., 1999; Latorre et al., 2007). In southern Chile, currently located within the core of the westerlies, new sedimentological and palynological records from fjords, peat bogs, and lakes point to more humid conditions during the early Holocene and decreasing rainfall thereafter (Figure 3(f)). These opposing rainfall trends across the northern margin and core of the westerlies point to antiphased intensity changes of the wind belt that resemble changes over the present seasonal cycle and do not necessarily require a latitudinal shift of the wind belt as a whole (Lamy et al., 2010).

The early Holocene optimum was not documented in the previously published SST record based on a shorter core (GeoB 3313-1) drilled at the same location as Site 1233. The shorter core only covers the last ~8 ka (Lamy et al., 2001, 2002). However, this shorter core provided very high-resolution records of SSTs, paleosalinity, paleoproductivity, and continental rainfall changes during the middle and late Holocene (Figures 4 and 5). The long-term trends in the records suggest a close coupling of marine and continental changes. Iron content decreases from the middle to the late Holocene, implying more humid conditions (Figure 4(a)). Similarly, SSTs as well as paleosalinities decrease and suggest increasing advection of subpolar water masses through the ACC and enhanced freshwater input in the Chilean Fjord region (Figure 4(b) and 4(c)). Finally, paleoproductivity generally increases throughout the record, consistent with

enhanced advection of high-nutrient/low-chlorophyll by the ACC combined with higher input of terrestrial micronutrients (Figure 4(d) and 4(e)). Similar continental rainfall and marine productivity changes have been found further north at 33° S (Hebbeln et al., 2002; Lamy et al., 1999).

The pattern of shorter term variability during the Holocene is more complex and many of the multicentennial- to millennial-scale variations in paleotemperatures and paleosalinities at site GeoB 3313 do not exactly match the reconstructed shifts of the westerlies in particular after ~5 ka BP. However, they do follow the millennial- to centennial-scale temperature changes recorded in Antarctica (Figure 5(a) and 5(b); Lamy et al., 2002). It has been speculated that this shift may be related to the onset of the modern state of ENSO (see later). The paleoproductivity records (Figure 5(d) and 5(e)) exhibit two century-scale excursions to higher values between 5.5 and 5 ka BP and shortly after 4 ka BP which do not exactly coincide with SST minima. Instead, they occur during cooling phases shortly after the two most significant increases in rainfall in the continental hinterland (Figure 5(c)). The iron record (Figure 4(a)) indicates that these rainfall augmentations terminated the less humid phase of the middle Holocene in southern Chile, pointing to a significant contribution of continent-derived micronutrients which resulted in an increase of marine productivity off southern Chile for several centuries (Lamy et al., 2002).

Studies on even shorter, that is, decadal- to centennial-scale timescales, are still rare. One such study has been performed on the latest Holocene sequence at ODP Site 1233 (Euler and Ninnemann, 2010). Planktonic and benthic foraminiferal $\delta^{18}\text{O}$ data suggest large decadal- and centennial-scale variations in surface and intermediate water physical properties that have been associated with shifts in tropical temperatures. Partly abrupt centennial-scale shifts in planktonic foraminiferal $\delta^{18}\text{O}$ data have been also observed further south at site MD07-3088 (~46° S) and interpreted in terms of significant SST and/or salinity variability (Siani et al., 2010). Within the fjords, there are indications of centennial-scale coolings during the past ~2000 years that partly coincide with the Northern Hemisphere Little Ice Age (Sepulveda et al., 2009).

South American Margin off Northern Chile and Peru

North of mid-latitude Chile, there are very few sedimentary records along the South American margin that cover the Holocene with a reasonable resolution because terrestrial sediment input is minimal off the hyperarid Atacama Desert. One of the few records comes from core GeoB 7112, located on the continental slope at ~24° S (Mohtadi et al., 2004). Though there is no direct SST proxy record available, several proxy records for marine productivity changes suggest that upwelling intensity was substantially reduced and the advection of warmer subtropical surface waters through a stronger PCCC was enhanced during the early and middle Holocene (Figure 3(b)). After ~5 ka BP, the pattern reversed, that is, upwelling became slightly stronger and surface waters were colder, consistent with the SST record at ~30° S off mid-latitude Chile (Figure 3(b) and 3(c)). As observed in most of the Chilean records further south, the variability in the records appears to be higher during the late Holocene, a pattern that may relate to more frequent and stronger El Niño events.

Figure 4 Paleoclimatic and paleoceanographic records from core GeoB 3313-1 off southern Chile covering the middle and late Holocene. Bold lines are ~2000-year moving averages (data from Lamy et al., 2002). (a) Iron contents interpreted as a proxy for rainfall and the position of the Southern Westerlies (high iron contents imply increased contribution of iron-rich volcanic Andean source rocks and decreased supply of iron-poor Coastal Range source rocks indicating decreased rainfall (Lamy et al., 2001)). (b) SST record tracing the advection of subpolar water by the ACC. (c) Sea surface salinity (SSS) reconstruction (5-point moving average) as a proxy for freshwater input in the Chilean Fjord region. (d) Corg contents and (e) biogenic opal contents are taken as proxies for paleoproductivity.

ENSO is also a major issue in the discussion of records from the Peruvian margin and adjacent tropical South America. An alkenone-based SST record from marine sediment core SO147-106KL (Figure 6(f); Rein et al., 2005), located on the continental shelf off Lima/Peru, shows a comparatively warm early Holocene, a cooling during the middle Holocene, and a significant late Holocene warming, culminating around 1.5 ka BP. The cooler SSTs would imply reduced El Niño events and mean La Niña-like conditions during the middle Holocene, consistent with SST records from the Eastern Pacific Cold Tongue (Figure 6(e); Koutavas et al., 2002; see section ‘Open Ocean Records’). These data are corroborated by terrigenous sediment flux rates, likewise based on core SO147-106KL, that suggest less El Niño-related rainfall events between 8 and 5.6 ka BP (Figure 6(g); Rein et al., 2005). In addition, lake records from

Equador (Moy et al., 2002) suggest reduced El Niño activity during the early and middle Holocene and significant enhancement of El Niño thereafter (particularly after ~5 ka BP; Figure 6(h)). In contrast to this broadly consistent picture, the presence of warm water mollusc shells that are presently not found along the coast of Peru, and $\delta^{18}\text{O}$ records from otoliths of sea catfish, imply warmer-than-present SSTs during the middle Holocene (Andrus et al., 2002; Figure 6(d)). Such warmer SSTs have been interpreted as reduced upwelling off Peru and thus a mean El Niño-like state (Andrus et al., 2002).

New Zealand/Australia

New alkenone SST records have recently become available from the southwest Pacific off New Zealand. A high-resolution

Figure 5 Paleoclimatic and paleoceanographic records from core GeoB 3313-1 off southern Chile focusing on the millennial- to centennial-scale variations compared to Antarctic ice core records. Data sets have been detrended by subtracting the long-term trends shown in Figure 4 (data from Lamy et al., 2002). (a) Short-term variability in Antarctic temperature shown as the first component of an empirical orthogonal function (EOF) analysis calculated from isotopic records from the Ross sea sector (Byrd and Taylor Dome sites; Masson et al., 2000). (b) SST record off Chile showing a significant positive correlation ($r=0.57$, $n=57$; significant on the 99.9% level after applying a 100-year time-resolution interpolation) to Antarctic temperatures until ca. 2000 BP (c) Iron contents of core GeoB 3313-1 indicating rainfall and the position of the Southern Westerlies. Paleoproductivity proxies (d) Corg content and (e) biogenic opal content. Vertical gray bars mark time intervals of century-scale increases in paleoproductivity as discussed in the text.

alkenone SST record based on core MD97-2120 ($\sim 46^\circ\text{S}$), located south of the Subtropical Convergence (Pahnke and Sachs, 2006) east of New Zealand, reveals a pronounced early Holocene temperature maximum lasting from ~ 12 to 8.5 ka BP with SSTs about $2\text{--}3^\circ\text{C}$ warmer than in the middle and late Holocene (Figure 7(b)). At the western continental margin of New Zealand, the alkenone SST record of core SO136-011GC ($\sim 44^\circ\text{S}$; Barrows et al., 2007) shows a somewhat less pronounced early Holocene temperature maximum and decreasing temperatures already beginning by ~ 9.5 ka BP and an additional cooling step in the late Holocene at ~ 2 ka BP (Figure 7(d)). A third alkenone SST record

based on core MD07-2121 ($\sim 40^\circ\text{S}$; Pahnke and Sachs, 2006), located east of New Zealand, north of the Subtropical Convergence, reveals maximum Holocene temperatures from ~ 9 to 6.5 ka BP which are, however, only $\sim 1\text{--}1.5^\circ\text{C}$ above late Holocene values (Figure 7(c)). Taken together, the southwest Pacific records reveal a Holocene pattern that is broadly similar to the southeast Pacific SST records (Figure 7(a)) and Antarctic ice core data sets (Figure 8(e) and 8(f)). Thus, the South Pacific mid-latitudes appear to be characterized by in-phase SST changes, at least regarding the general trends, similar to the pattern derived for the last glacial period.

Figure 6 Paleoclimatic data from the subtropical and tropical Pacific and other terrestrial records relevant for the discussion of long-term ENSO changes. (a) Huascarán $\delta^{18}\text{O}$ record as a proxy for temperature changes in tropical South America (Thompson et al., 1995). (b) SST record from the western Pacific Warm Pool (stacked data from several cores as in Stott et al. (2004)). (c) Composite alkenone SST index based on five SST records from the eastern Pacific equatorial cold tongue that have been averaged for nonoverlapping 1000-year time windows (Koutavas and Sachs, 2008). (d) Warm phase recorded in coastal Peru (Andrus et al., 2002). (e) Mg/Ca-based SST record from the eastern Pacific cold tongue (Koutavas et al., 2002). (f) Alkenone-derived SST record from the Peruvian shelf (Rein et al., 2005). (g) Lithic flux record from the Peruvian shelf as a proxy for El Niño-related torrential rainfall events in the region (Rein et al., 2005). (h) Frequency of El Niño events reconstructed from turbidity frequency recorded in a lake in Ecuador (Moy et al., 2002).

Figure 7 Alkenone-based SST records from the New Zealand continental margins compared to the SST record from ODP Site 1233 off southern Chile and Antarctic ice core records. Gray bar marks early Holocene maximum warm phase as defined at ODP Site 1233 (Kaiser et al., 2005). (a) SST record from ODP Site 1233 (Kaiser et al., 2005; Lamy et al., 2007). (b) SST record from core MD91-2120 (Pahnke and Sachs, 2006). (c) SST record from core MD91-2121 (Pahnke and Sachs, 2006). (d) SST record from core SO136-GC11 (Barrows et al., 2007). (e) δD record from the Taylor Dome ice core as a proxy for western Antarctic temperature (Steig et al., 1998). (f) δD record from the Dome C ice core as a proxy for eastern Antarctic temperature (EPICA Community Members, 2004).

Additionally, core MD07-2121 provided more indirect information on postglacial circulation changes off eastern New Zealand through changes in terrigenous sediment flux (Gomez et al., 2004). This record suggests a strengthened East Cape current from ~ 9 to 3.5 ka BP and reduced inflow of subantarctic water masses. A major sediment texture shift in this core at ~ 4 ka BP has been correlated to a similar shift in terrestrial floodplain and marine shelf records. This shift has been correlated with the onset of increased storminess connected to the establishment of modern intensified atmospheric circulation, strongly influenced by ENSO. Enhanced ENSO

activity during the late Holocene is consistent with the records from the South American margin of the Pacific.

Antarctic Peninsula (Palmer Deep)

Along the Pacific margin of the Antarctic Peninsula, high-resolution and well-dated sedimentary records have been recovered from the Palmer Deep, an inner shelf basin (Figure 1). The records from ODP Site 1098 cover the last ~ 13 ka, often in centennial or better resolution, and can be subdivided into four different intervals (Figure 8(b); Domack et al., 2001).

Figure 8 Paleoenvironmental record from Palmer Deep (Antarctic Peninsula) compared to the SST record from ODP Site 1233 off southern Chile and Antarctic ice core records. (a) SST record from ODP Site 1233 (Kaiser et al., 2005; Lamy et al., 2007). (b) Magnetic susceptibility record from ODP Site 1098 at Palmer Deep (Domack et al., 2001). High values are interpreted to reflect stronger terrigenous sediment input and reduced marine productivity coinciding with enhanced input of ice-rafted detritus (IRD) (Domack et al., 2001). Shown are also the major Holocene intervals that have been defined for Palmer Deep (reproduced from Domack E, Leventer A, Dunbar R, Taylor F, Brachfeld S, and Sjunneskog C (2001) Chronology of the Palmer Deep site, Antarctic Peninsula: A Holocene paleoenvironmental reference for the circum-Antarctic. *Holocene* 11: 1–9). (c) δD record from the Taylor Dome ice core as a proxy for western Antarctic temperature (Steig et al., 1998). (d) δD record from the Dome C ice core as a proxy for eastern Antarctic temperature (EPICA Community Members, 2004).

Deglaciation lasted until ~ 11.5 ka BP and was followed by a climatic reversal ending abruptly at ~ 9 ka BP. Thereafter, a middle Holocene ‘climatic optimum’ is recorded, characterized by enhanced marine productivity and decreased input of ice-rafted detritus (IRD). After ~ 4.7 ka BP, productivity decreased and IRD input increased, leading to a ‘neoglacial’ phase since ~ 3.4 ka BP. This is consistent with enhanced IRD content in South Atlantic sediment cores. Coeval changes were recorded in proxy records for deepwater conditions at the ~ 1000 m deep drilling site. During the middle Holocene ‘optimum,’ bottom waters were poorly ventilated, suggesting a reduction of circumpolar deepwater production. This, in turn, is possibly related to reduced North Atlantic Deepwater production (see (Thermohaline Circulation), providing a link to Northern

Hemisphere climate (Ishman and Sperling, 2002). Bottom water conditions changed rapidly during the late Holocene with variable inflow of circumpolar deepwater, possibly related to short-term changes in the position of the Southern Ocean sea-ice margin and the position of the ACC providing a link to the Chile margin records.

Bentley et al. (2009) recently reviewed the Holocene paleoenvironmental record of the Antarctic Peninsula region and their study revealed significant differences between terrestrial and marine records. This is particularly manifested for a pronounced warming period from ~ 4.5 to 2.8 ka BP seen in the terrestrial records that overlaps with the beginning of the ‘neoglacial’ phase in the marine records of Palmer Deep.

Open Ocean Records

Away from the continental margins, high-resolution Holocene records are rare in the mid- and high-latitude Pacific, where even the glacial–interglacial patterns are not well documented. A radiolarian-based SST record from the southwest Pacific recovered from the northeastern flanks of the Bounty Plateau (~900 km east of the New Zealand's South Island) reveals a 2–3 °C warmer early Holocene warm period between ~10 and 5 ka BP (Luer et al., 2009), roughly similar in timing and amplitude to the New Zealand and southeast Pacific margin records. In the Pacific Sector of the Southern Ocean, Bradtmiller et al. (2009) compared glacial and Holocene opal flux rates based on 31 cores and found that Holocene opal fluxes were lower north of the Polar Front and higher south of it. However, the resolution of their records does not allow for discussing Holocene temporal trends in these data sets.

In the tropics, Holocene paleoceanographic records have been derived from sediment records of the Western Pacific Warm Pool and the Eastern Pacific Cold Tongue (Figure 1; Koutavas et al., 2002; Stott et al., 2004). Today, both these are regions that are particularly sensitive to SST changes connected to ENSO. The western Pacific records display a slight (~0.5 °C) cooling over the past 10 ka, while the Mg/Ca-based SST record from the Cold Tongue core V21-30 reveals a broad middle Holocene cooling on the order of 1 °C (Figure 6(b) and 6(e)). These data suggest enhanced zonal SST gradients during the middle Holocene that decrease after ~5 ka, a pattern that would suggest a mean La Niña-like state of ENSO during the middle Holocene and a larger impact of El Niño events during the later part, broadly consistent with the records based on core SO147-106KL on the Peruvian shelf (Figure 6(f) and 6(g)). The above-mentioned SST records are both Mg/Ca-based. More recently, several alkenone-derived SST records from the Cold Tongue have been published that are all characterized by a consistent warming in the range of ~0.5–2 °C over the course of the Holocene (Figure 6(c); Koutavas and Sachs, 2008; Leduc et al., 2010). This warming trend has been explained by changes in low-latitude boreal winter insolation, assuming that the alkenone-producing haptophytes preferentially bloom during this season (Leduc et al., 2010). Moreover, Leduc et al. (2010) showed that the Mg/Ca-derived SST records from the eastern tropical Pacific are much more heterogeneous, due to complex combinations of different ecological preferences of planktonic Foraminifera and the impact of carbonate dissolution. Therefore, Mg/Ca SST records are more complicated to interpret, in terms of the overall temperature trends. However, the general pattern of enhanced zonal SST gradients during the early to middle Holocene, compared to the late Holocene, remains valid, based on comparisons with the alkenone-based SST reconstructions (Figure 6(b) and 6(c)).

Forcing Mechanisms

Orbital Timescales

The major 'long-term' trends within the postglacial records from the South Pacific are most likely related to orbital forcing. During the early Holocene, summer insolation was higher in

the Northern Hemisphere and reduced in the south, resulting in distinct seasonality differences between the two hemispheres. In the course of the Holocene, austral summer (December–February) insolation and seasonality increase toward the present. These changes are induced by precessional forcing, whereas changes in the obliquity of the Earth's axis produce hemispherically symmetric patterns in annual insolation (Figure 9). Throughout the Holocene, annual insolation decreased in high latitudes and increased in the tropics.

Most extratropical SST records from the South Pacific do indeed show a trend toward colder temperatures from the early to late Holocene, a pattern that is also found in some (but not all) Antarctic ice core records. In addition, atmospheric and oceanographic changes appear to be closely coupled, suggesting, for example, simultaneous latitudinal shifts of the northern margins of the Southern Westerlies and the ACC system on orbital timescales (see earlier). A recent model of global surface ocean changes during the Holocene shows early Holocene SST about 0.5 °C warmer in the Southern Ocean compared to ~1 °C warming in the Arctic Ocean (Liu et al., 2003). However, based on the paleorecords, the observed cooling in the course of the Holocene was substantially larger, for example, on the order of 1.5–2 °C in the Chilean margin records (Figure 3). Additional SH warming during the early Holocene might be attributable to changes in the global ocean circulation which involve a bipolar seesaw-like surface temperature pattern. For the early Holocene, such a mechanism has been invoked to explain warm temperatures in the Southern Ocean and Antarctica (Masson et al., 2000) and is consistent with a reconstruction of the Atlantic meridional overturning circulation strength in the North Atlantic (McManus et al., 2004; Figure 9(f)) (see [Thermohaline Circulation](#)).

Precessional changes in seasonal insolation might have affected the records in the subtropics and tropics. Reduced early and middle Holocene summer insolation in the SH could have, for example, strengthened the Hadley Cell circulation in the eastern Pacific as the South American summer monsoon was largely reduced (Figure 9). This would indirectly affect the position of the Southern Westerlies and the position of the northern margin of the ACC, contributing to the observed early Holocene warming in the southeast Pacific and dry conditions in central Chile. At the same time, however, the core of the Southern Westerlies over southernmost Chile was enhanced (see earlier). During the late Holocene, warming in the eastern tropical Pacific and cooling further south possibly enhanced the mid- to low-latitude SST gradient resulting in stronger westerlies at their northern margin (Lamy et al., 2010). In addition, seasonal insolation changes largely affect ENSO dynamics and the position of the Intertropical Convergence Zone (ITCZ). Modeling studies (Cane, 2005) suggest that the ITCZ was located north of its present position and the frequency and strength of El Niño events were strongly reduced during the early and middle Holocene, consistent with reconstructions based on paleodata from the eastern tropical Pacific and adjacent subtropical South America (Figure 6).

Millennial–Centennial Timescales

Millennial- to centennial-scale climate patterns are only documented in a few records in the South Pacific realm.

Figure 9 Orbital forcing parameters and modeled ENSO variability during the Holocene. (a) Obliquity (data from Berger and Loutre, 1991). (b) Precession index (data from Berger and Loutre, 1991). (c) Austral summer insolation (December–February; reproduced from Berger and Loutre, 1991). (d) Number of El Niño events per 500 years (years with $>3^{\circ}\text{C}$ NINO3 SST anomaly; data from Clement et al., 2000). (e) El Niño strength shown as the mean amplitude of the $>3^{\circ}\text{C}$ NINO3 SST anomaly in a 500-year window (data from Clement et al., 2000). (f) $^{231}\text{Pa}/^{230}\text{Th}$ record from a subtropical North Atlantic sediment core taken as a proxy for the strength of the Atlantic meridional overturning circulation (AMOC; data from McManus et al., 2004).

The high-resolution record of rainfall variability from the southern Chilean margin (41°S) suggests two dominant bands of variability with cycles of ~ 900 and ~ 1500 years (Lamy et al., 2001). Comparisons of band pass filters with records from Antarctica and tropical South America (Sajama ice core) show a close connection to the tropics, particularly regarding the ~ 900 -year cycle (Figure 10) most likely involving changes in the strength of the Hadley Cell over the southeast Pacific and adjacent South America (Lamy et al., 2001). On the other hand, the correlation to climate conditions in Antarctica on millennial and multicentennial

timescales reveals a major phase shift at ~ 4 ka BP (Figure 10) that roughly coincides with the onset of modern ENSO. A shift at the transition from the middle to the late Holocene is also evident in the comparison of the short-term rainfall fluctuations to surface ocean changes. This suggests a mismatch between millennial- and multicentennial-scale variability in atmospheric (i.e., Southern Westerlies) and oceanographic (i.e., southern PCC and ACC) circulation patterns during the late Holocene (Figure 6). The proposed explanation is that temperatures in the southern PCC during the late Holocene have probably not been affected by changes in ENSO (Lamy

Figure 10 Comparisons of 900-year band pass filters of Chilean rainfall record with records from Antarctica and tropical South America. (a) Dust content of the Sajama ice core (thin line; data from Thompson et al., 1998) interpreted as a proxy for the aridity of the Bolivian Altiplano and the Hadley cell intensity over the southeast Pacific and tropical South America. (b) Iron content from core GeoB 3313-1 interpreted as a proxy for rainfall and the position of the Southern Westerlies (thin line = 5-point moving average; data from Lamy et al., 2001). (c) δD record of the Taylor Dome ice core (thin line = 5-point moving average) interpreted as a proxy for atmospheric temperature in coastal Antarctica and the extension of Antarctic sea ice (data from Steig et al., 1998). Thick lines represent Gaussian band pass filter centered at 900 years ($0.00111 \pm 0.0002 \text{ year}^{-1}$). The bandwidth chosen covers the dominant periodicities around 900 years in the records as indicated by spectral analyses (data from Lamy et al., 2001). High iron contents in the Chilean record correlate to high dust contents in the Sajama ice core in the 900-year band. Correlation of iron contents to δD record of the Taylor Dome ice core shifts from positive in the middle Holocene (high iron contents correlate to high δD values) to negative in the late Holocene (high iron contents correlate to low δD values).

et al., 2002). Modern ENSO-related SST anomalies only reach south to $33\text{--}36^\circ\text{S}$ (Strub et al., 1998), whereas meteorological studies suggest a strong effect of ENSO on rainfall anomalies in both central and southern Chile (Montecinos and Aceituno, 2003). The possible global origins of the ~ 900 and ~ 1500 cycles that are found in a number of Holocene records on a global scale are discussed by Lamy et al. (2001). The ~ 900 -year cycle could be related either to subtle changes in orbital parameters and/or to solar activity, as it is also present in the $\Delta^{14}\text{C}$ record from tree rings. Interestingly, long-term grain-size variability at Palmer Deep of the Antarctic Peninsula is characterized by ~ 1800 -year cycles that have been related to lunar tidal cycles (Warner and Domack, 2002) or they may simply represent multiples of the ~ 900 -year cycle. The high-resolution Palmer Deep records also suggest substantial variability of oceanic and atmospheric circulation close to Antarctica on shorter, centennial

timescales (e.g., ~ 200 and ~ 400 years, interpreted as solar variability) and even on multidecadal scales (Domack et al., 2001).

Introduction, Why Study Paleoclimatology?

The Earth's climate constantly changes, exhibiting variations both temporally and spatially. In a shorter timeframe of every other year or so, climatic changes such as those resulting from El Niño events, prominently affect regions throughout the globe. In much longer timeframes, such as tens of thousands of years ago, dramatic climatic changes have occurred, associated with environmental changes such as the equatorward expansion of large ice sheets and characteristics of vegetation assemblages much different than those seen today. A thorough understanding of the causes of climatic variations is important for society because of the effects of climate on human activities such as agriculture, water resources, energy, biological productivity, and environmental quality. These variations include not only present-day natural variability, such as periodically recurring droughts and floods, but also include future climatic changes. In particular, during the last few decades, scholars have shown increasing concern about human-induced climatic changes such as a doubling of carbon dioxide concentration, which may cause global warming (IPCC, 2001). Some future global warming scenarios from computer models predict potentially widespread catastrophic consequences for society, such as widespread drought at mid-latitudes and unprecedented rapid warming in the Arctic.

Paleoclimatology is defined as the study of climates during any part of the geological past (Bradley, 1999), and specifically deals with climates prior to the period of modern instrumental records, using proxy data (natural phenomena that are climate-dependent) to reconstruct past climates, and using computer models (hereafter referred to as general circulation models (GCMs)) to explain the causes of past climatic change (Kohfeld and Harrison, 2000; Figure 1). The Quaternary period, defined as encompassing the last 2.6 My, is unique in the field of paleoclimatology. This is due to the availability of copious

amounts of data by which to thoroughly understand the climate system at critical times of the past. The study of past climates can greatly help our understanding of climatic change by:

1. Providing a longer-term perspective than the modern instrumental record on understanding the controls, magnitudes, and spatial as well as temporal aspects of climatic change. For example, failure of the Asian monsoon may have occurred more frequently in the past, ranging from several centuries to many thousands of years ago, and the examination of many such cases may provide clues on how particular controls (e.g., El Niño events, mountain uplift) govern monsoonal activity (An et al., 2001; Morrill et al., 2003). Paleoclimatology also provides a longer record of greenhouse gas concentrations and other phenomena linked to climatic forcing mechanisms, and assessment of these longer records, such as carbon dioxide concentrations, may provide different interpretations on the timing of global warming (Ruddiman, 2005).
2. Testing the accuracy of GCMs. Some paleoclimates have boundary conditions and forcing mechanisms that were much different than today and what is expected for the future (Figure 2), especially at longer time scales, such as the peak of the last glaciation around 21 000 years ago (Webb, 1998) and just before the onset of the Quaternary when tectonic uplift played a prominent role in climatic change (Berger, 1992; Ruddiman et al., 1997). However, the variability of forcing mechanisms also exhibits different characteristics within shorter time scales, such as pre-industrial carbon dioxide concentrations in the last 500 years (Robertson et al., 2001). Since the forecasting of future climate relies on the use of GCMs, if model simulations of paleoclimate correspond with those reconstructed from fossil data, we could place more confidence in using these GCMs for simulating and understanding future climatic changes, such as global warming.

3. Providing a longer climate record of natural variability. We need a clear understanding of natural climatic variability, in order to delineate natural from anthropological variability. As a result of increased anthropogenic effects on climate, such as increasing population and urbanization, it is difficult to disentangle these two factors. The general rise in global mean temperature since the mid-1800s provides a clear example (Mann et al., 1998), but other prominent warm periods in the past provide valuable information on how the climate systems operate to further assess future climates (Webb et al., 1993). Scholars know that increased urban heat island effects and carbon dioxide concentrations may play important roles, but could the temperature rise also be a natural response from a colder period known as the Little Ice Age in the seventeenth to nineteenth centuries when carbon dioxide concentrations were lower than today?

Figure 1 The two basic fundamental approaches in paleoclimate research: (1) the modelling approach and (2) the paleoclimate reconstruction ('data') approach. A common theme that has emerged in paleoclimatology in the last three decades is the synthesis and analysis of 'data/model' comparisons.

The first three reasons for studying paleoclimate help to understand the controls of climatic change and how the climate system operates. However, paleoclimatology is multidisciplinary, benefiting from several fields to understand and reconstruct climates of the past, thus offering important information for paleoecologists. This leads to a fourth important reason for studying paleoclimatology.

4. To provide detailed paleoclimatic records to understand the role of climatic change on ecosystems and society. This importance is best illustrated through some examples. Paleoecologists interested in vegetation histories of a species need to incorporate the role of climatic change over time scales of thousands to millions of years (Overpeck et al., 2003). Archaeologists studying the changing lifestyles of past societies need detailed paleoclimatic records to assess the role of climatic changes (Weiss and Bradley, 2001). The latter example also proves useful for scholars studying climate impact assessment and reconstructing natural hazards, such as the effects of widespread severe drought (Figure 3; The North American Drought Atlas, 2004). Some paleoclimatic proxies possess subseasonal resolution that can sometimes detect specific meteorological events, such as hurricanes and severe flooding, that affected society (Figure 4; Mock et al., 2006). Although most societies functioned differently in the past than they do today, we can learn much from climate impact studies of the past and apply them to understand potential future impacts (Jones et al., 2001).

Some Recent Developments in Paleoclimatology

Prior to 1970, much paleoclimatological research focused primarily on climatic reconstructions that described what happened, with studies involving a variety of different proxy data

Figure 2 Some examples of boundary conditions of climate over time. Top: June mid-month insolation at 60°N in the last million years; note the cyclical behavior of insolation that represents variations in the Milankovitch orbital parameters. Tropical cyclone data were taken from the HURDAT database and archival collections owned and compiled by Mock and colleagues at South Carolina.

types (Wendland, 1991). Radiometric dating techniques, such as radiocarbon and potassium-argon dating, provided a quantitative means to date past climatic change. Paleoclimatic research was propelled by the establishment of numerous research centers that specialized in particular proxy data and dating methods. For example, dendroclimatology, the study of tree-rings, accelerated after the establishment of the Laboratory of Tree Ring Research at the University of Arizona, USA in 1937. Similar dendroclimatic laboratories were established later at Columbia University in New York, the University of Arkansas, the Climatic Research Unit, University of East Anglia, United Kingdom, and the Swiss Federal Institute for Forest, Snow, and Landscape Research, Switzerland, among many. Research centers focusing on other proxies such as palynology also emerged, including the University of Minnesota in the United States, University of Cambridge in England, Lund University in Sweden, the University of Bern in Switzerland, and the Russian Academy of Sciences, Institute of Geography in Moscow. Similarly, prominent research centers in Quaternary paleoceanography emerged as well, with some notable centers being based at Cambridge University, Brown University, and Columbia University. As time progressed, improvements and new techniques in data analysis were developed at

prominent research centers such as the Quaternary Research Center in the United States, and the Xian Laboratory of Loess and Quaternary Geology at the Chinese Academy of Sciences. Newly trained academics that graduated from these research centers started research centers of their own, building up paleoclimatic databases.

Beginning in the early 1970s, the development of high-speed computers fostered a new type of paleoclimatology that specializes in analyzing large paleoclimatic datasets (Wright and Bartlein, 1993). Some interpretive tools in paleoclimatic analyses are qualitative in nature, which continue to this day and can involve analyses from local to hemispheric scales (Figure 1). Earlier quantitative studies applied basic transfer functions to convert proxy variables into climate variables, which also involved the calibration of modern climatic data with modern environmental data. The modern relationships were applied to fossil environmental data to quantitatively reconstruct past climate (Webb and Bryson, 1972). As the datasets grew, so did the sophistication of quantitative interpretive tools for analyzing large-scale paleoclimatic datasets (Mann et al., 1998; Prentice et al., 1991). For example, the recently compiled North American Drought Atlas, which provides geographical maps of drought severity by year, is based

on a geographical network of 835 tree-ring sites (Figure 3; Cook and Krusic, 2004). Many paleoclimatic data networks are now available through the World Data Center-A for Paleoclimatology (WDC-A) at Boulder, CO (Webb et al., 1994), and other mirror sites around the world at Johannesburg in South Africa, Lanzhou in China, Mendoza in Argentina, Nairobi in Kenya, and Pune in India (Eakin et al., 2003). These data networks range from the regional to global scale, with examples being the International Tree Ring Database (Grissino-Mayer and Fritts, 1997) and the Global Pollen Database.

The computer revolution also created a paleoclimatic perspective for dealing with GCMs. These models are similar to those used in daily weather forecasting but instead the principles are applied to simulate large-scale climate patterns of the past. Earlier attempts focused mostly on the atmosphere, but paleoclimatic modeling has evolved to link atmospheric models with detailed feedbacks as they relate to processes in the biosphere, lithosphere, and hydrosphere (Kohfeld and Harrison, 2000; Kutzbach et al., 1998). Considerable attention has been paid to ocean-atmospheric feedbacks. GCMs have been used to simulate paleoclimates ranging from a few hundred to millions of years ago (Kutzbach, 1992), as well as selected timeframes and phenomena of interest in the past (LeGrande et al., 2006; Seager et al., 2005). As opposed to paleoclimatic proxy data, which independently reconstruct 'what happened' (Figure 1), GCMs explain 'why things happened' and thus are an extremely useful tool for paleoclimatologists to test hypotheses concerning the causes of climatic change by comparing simulation results with those derived from proxy data (Harrison and Prentice, 2003; Mahowald et al., 1999). Within the last two decades, many different paleoclimatic modeling groups have emerged and remain active; some of these include modeling activities at the National Center for Atmospheric Research in Boulder, CO, the Hadley Centre in the United Kingdom, the Canadian Centre for Climate Modeling and Analysis, the Max-Planck Institute for Meteorology at Bremen University, the Laboratoire de Météorologie Dynamique in France, and the Goddard Institute of Space Studies in Maryland, USA.

Increased resolution in dating techniques and the growing body of paleoclimatic evidence, particularly from ice cores and marine sediments from the North Atlantic, indicate that abrupt decadal-centennial scale changes in climate occurred in the distant past, that are much different in magnitude and character than those observed in the modern instrumental record (Clark et al., 1999; Labeyrie et al., 2003; Overpeck, 1996). These changes are significant for society, for we now know that such abrupt climatic changes may occur within a single human lifetime. Paleoclimatic records thus offer the only means to test whether our predictive models can simulate such future changes. Modeling attempts have been made to simulate the causes and nature of these abrupt changes. These model runs are enabling scientists to conduct detailed data-model comparisons at the hemispheric and global scales (Clark et al., 2002). However, to date, most modeling studies on these events are still focusing on providing sensitivity tests to assess potential forcing mechanisms. We are only beginning to document and understand the controls and causes of these abrupt changes, and such questions will continue to be important for the paleoclimatology community for years to come.

Organization of the Articles

Numerous articles in this encyclopedia describe how paleoclimatology can contribute toward a further understanding of the climate system of the past. These articles represent the most up-to-date information from the paleoclimate research community. Bartlein provides an overview of the concepts on how climate varies at different time scales, ranging from inter-annual to pre-Quaternary, and how we can interpret some reconstructions from proxy data in relation to climate model simulations. Shuman further discusses the details of how Quaternary scientists use different data, methods, and tools for reconstructing past climates, including data/model comparisons as well as various geographical, quantitative, and qualitative approaches. Harrison describes the current status of data/model comparisons in paleoclimatology.

Several articles provide more details on important forcing mechanisms that affect feedbacks in the climate system, and these are important parts of climate model simulations. The importance of the thermohaline circulation on past climates is well-known, and Rahmstorf describes how changes of various fluxes in the oceanic environment may relate to glacial fluctuations and other rapid climatic changes. Brozkin illustrates that although climate is a prominent control on geographical aspects of the terrestrial biosphere, various other factors in the terrestrial biosphere may also alter feedbacks that affect the climate system. Tegen describes the importance of atmospheric dust on climate at different time scales, including attempts to quantify its magnitude. Shindell illustrates how solar and volcanic forcing are related to climatic variability at different time scales, also approaching this from a modeling perspective.

Another group of articles describe specifics on the nature of climate variability at different time scales from throughout the Quaternary and back into the Pliocene. Poore provides an important review of pre-Quaternary climate and forcing mechanisms that helps assess the onset of paleoclimatic variations in relation to multiple glacial and interglacial cycles in the Quaternary. Owen also contributes valuable information on pre-Quaternary paleoclimate, focusing attention on tectonics and continental configurations, but also addressing several different aspects of tectonics. Berger describes an overview of the astronomical theory of Quaternary paleoclimate, discussing the prominent orbital cycles as well as the role of carbon dioxide in climate change.

The late Pleistocene/Holocene timeframe of approximately the last 130 000 years has been the focus of many studies; some continuous, high-resolution proxies (e.g., ice cores) and climate modeling researchers have expressed a high degree of confidence in the prominent climate forcing mechanisms. Montoya illustrates the details of modeling simulations of the paleoclimate of the Last Interglacial (around 125 000 years ago), which is a time when orbital factors were conducive to widespread warmth in many parts of the world. Broccoli discusses the nature of research on model simulations of the Late Glacial Maximum (LGM) of 21 000 years ago, and demonstrates the importance of nonorbital factors such as ice-sheet size, dust, and greenhouse gases. Labeyrie illustrates that there are also more rapid, millennial-scale changes that occur within the orbital-induced changes and prominent glacial-interglacial

cycles. These events, commonly referred to as Dansgaard/Oeschger and Heinrich events, are prominent in many high-resolution paleoclimatic records but more work is needed on modeling efforts. Barber describes a regional example, illustrating how peatland records in northwest Europe can aid in multiproxy efforts of reconstructing past regional climate patterns through the Holocene.

Another group of articles describes the nature of paleoclimatic records at time scales within the last 2000 years, as well as addressing their importance to contemporary climatic issues and societal impacts. Smith provides an overview of dendroclimatology, which is a prominent paleoclimate proxy with annual temporal resolution for many terrestrial regions. Chenoweth provides an overview of research on historical climate reconstruction from archival materials, some of which include data resolved at the daily level. These materials are mostly limited to the last several centuries, depending on the geographical area of interest. Mann elegantly describes how different high-resolution proxies, including tree-rings and historical evidence, can be combined to quantitatively reconstruct temporal and spatial patterns of high-resolution climate over the last millennium. These reconstructions capture many important, dominant climatic modes that are seen in the modern instrumental record, but they also reveal changes in the importance of these modes over time. Liu provides an overview on paleotempestology, the reconstruction of past hurricanes and typhoons that encompass time scales from the last few hundred years to most of the Holocene, based on several different proxies. He also provides discussion of some of the forcing mechanisms that govern past hurricane activity. C Mock provides two articles on paleo-ENSO (El Niño-Southern Oscillation, Paleo-ENSO) and paleodrought, respectively. As with paleotempestology, both of these phenomena are climatic extremes of high interest to society that can be reconstructed from paleoclimatic proxies, also extending through the Holocene. Last, Schneider and Mastrandrea illustrate how longer records from paleoclimatology aid society in further understanding anthropogenic global climate change, particularly global warming, that may occur in the future.

Introduction

Climate varies. Although often defined in terms of ‘average weather,’ or the expected values of statistical parameters over some interval, when looking at climatic time series plotted over any interval (from years to millions of years) for any location (from point to globe), one sees the tremendous variability of the record. Typical values or central tendencies for a climate variable can indeed be observed, as can general ranges of values within which the variable remains. However, most of the time a climate variable (and that part of the climate system it represents) might be described as continuously heading from one level to another, never remaining at a particular value for long. Intervals with low variability are generally the exceptions rather than the rule in climatic time series. Here, ‘variance’ refers to the statistical quantity (the mean of the squared deviations about the long-term mean); ‘variability’ refers to the tendency of records to vary; and ‘variation’ refers to a particular portion or feature of a record or to the time-course of a variable.

Variability of climate occurs across a range of timescales (the focus of this article) and does so in a fashion that exhibits considerable structure. Rather than displaying a simple pattern of variability that increases as a function of time span or record length, as with a system that obeyed simple scaling laws (Kantz and Schreiber, 2004), the climate system has some preferred temporal scales of variability that reflect the nature of the external forcing of the climate system or the internal time constants of the components of the climate system itself (Saltzman, 2002). Although some of these external controls are intrinsically periodic, such as the variations of the Earth’s orbital elements (Imbrie et al., 1984), most are not. Similarly, the internally generated variations of climate, including some that might be described as ‘cyclical,’ are best described as only quasiperiodic.

One approach for characterizing or describing the variability of climate is the variance spectrum, which displays a statistical property, variance, as a function of the period or frequency of the variation. ‘Peaks’ in such a display point to particular frequencies or timescales at which variability is concentrated. A schematic version of a variance spectrum for the climate system for timescales from a year to a billion years is illustrated later. In addition, evolutionary or ‘moving-window’ spectral analyses can be used to reveal the changing importance over time of variability on different timescales, and two examples are also described.

Perhaps owing to its heritage in signal processing (Jenkins and Watts, 1968) and to its wide application in developing the astronomical (Milankovitch) theory of climate change, the application of the variance spectrum to illustrate timescales of climate variability naturally directs a user toward the periodic or oscillatory features in a time series. Hence, explanations of those features usually invoke some kind of regular cyclical mechanisms, either external (Sun, Moon, planets) or internal (oscillatory ‘climate-modes’).

Several factors may predispose researchers to see cycles in time series (in addition to the tendency to see order in apparent chaos). These include the tendency for climate variables to vary between some general limits, and the consequences of applying some common data-analytical methods, such as the variance spectrum or moving-average filters. A few examples discussed later will show how spurious periodicities can arise when characterizing the timescales of climate variability.

An alternative approach for describing the nature of climate variability is to describe the characteristic features or kinds of variations that recur in many climatic time series. There is a relatively small number of kinds or patterns of variation that climatic time series display. These occur across a range of different timescales and can be distinguished by the extent of their influence throughout different levels in the climate-system hierarchy, their predictability, and the extent to which they represent progressive trends, or regular or irregular variations.

Climate Variations

The Hierarchy of Climate System Controls and Responses

Climatic variations occur within a hierarchy of controls and responses, which begin at the highest level with the external controls of climate, proceed through global, hemispheric, continental, and regional scales, and end with the variations of individual climate variables at specific locations at the lowest level (Bartlein, 1997). Responses at any one level of the hierarchy become the controls of variations of the components at lower levels. For example, on timescales of 10^4 – 10^6 years, ice sheets are dependent variables in the climate system, governed by orbitally controlled variations in insolation. At shorter timescales (10^4 – 10^3 years), ice sheets act as independent variables that have an important influence on global temperatures and atmospheric circulation. With the exception of the annual cycle, there is a general tendency for the variations of components at higher levels in the hierarchy to exhibit more long-term variability, while those at lower levels experience more short-term variability.

The existence of this hierarchy also has implications for attempts to explain the variations at a particular location. For example, although climatic variations at a location are ultimately governed by global-scale controls, a specific paleoclimatic record is not representative of the general state of the global system. This situation arises because the intermediate controls and responses have the potential of reinforcing, canceling, or even reversing the longer-term global trends. Gradual changes in large-scale controls may sometimes produce abrupt local changes when atmospheric circulation is reorganized. Conversely, abrupt changes in the large-scale circulation may produce warming in some regions and cooling or no change in others, as can be seen in the spatial anomaly patterns of year-to-year variations of climate. Consequently, while it may be

difficult or even impossible to ascribe a particular climate variation at a location to a specific configuration of higher-level controls, shorter-term variations at lower levels are strongly conditioned by the particular state of system at higher levels. Therefore, any discussion of the timescales of climatic variability should explicitly acknowledge the spatial scale or extent of the system being discussed.

Some Representative Paleoclimatic Time Series

To illustrate the spectrum and characteristic features of climatic variations across a range of timescales, it will be useful to examine some representative time series. **Figure 1(a)** is a composite global oxygen-isotope record that provides a general description of the global cooling during the Cenozoic that culminated in Quaternary glacial–interglacial variations (Zachos et al., 2001). This record was constructed from a number of individual records, which can be plotted as individual points, but not as time series. In addition to the general trend, individual steps toward colder conditions are evident. **Figure 1(b)** shows another composite record, this time constructed by superimposing or ‘stacking’ individual records to form a single series (Lisiecki and Raymo, 2005). This shows the periodic variations in global ice volume associated with the Earth’s orbital elements, as well as the changes in the relative importance of the variations at different timescales.

Oxygen-isotopic variations from the GISP 2 Greenland ice-core record are shown in **Figure 1(c)** (Stuiver et al., 1997). This series shows the large-amplitude millennial timescale variations known as the Dansgaard–Oeschger cycles that occur throughout most of the record, the Younger Dryas climate reversal (12 800–11 600 years BP, Alley et al., 1993), and the much lower amplitude variability in this record during the Holocene. **Figure 1(d)** shows a speleothem oxygen-isotope record that exhibits the long-term decline in the strength of the East Asian monsoon, along with decadal-to-century variations throughout the Holocene, a pattern typical of many Holocene records (Mayewski et al., 2004). **Figure 1(e)** illustrates a reconstruction of Northern Hemisphere temperature anomalies over the past two millennia (Moberg et al., 2005), along with the observational record of the past century (Hansen et al., 2006). Like other similar reconstructions (Mann and Jones, 2003), this record shows interannual-to-century-scale variations, and the unprecedented increase in temperature over recent decades.

These series do not illustrate the entire range of variations experienced by the climate system over the Quaternary. A network of time series that span the different timescales and levels in the hierarchy would be required, and such a network does not exist. However, this set of series does illustrate the variety of characteristic features in climatic time series that will be discussed further later.

The Spectrum of Climate Variability

There are several ways of schematically illustrating the nature of climate variability (in addition to simply plotting representative series). These include ‘powers-of-ten’ presentations (Webb, 1989), wherein climatic time series of different duration (e.g., the past 100 000, the past 10 000, the past 1000 years) are

plotted and examined; portrayal of the variance spectrum of climatic time series, which reveals the relative importance of variations at different timescales (Mitchell, 1976; Shackleton and Imbrie, 1990); or ‘scale diagrams’ that indicate the characteristic temporal and spatial scales on which the particular components of climate vary (McDowell et al., 1991). Of these, the variance spectrum has often been used to illustrate the relative importance of climatic variations on different timescales.

The Variance Spectrum

The variance spectrum displays the relative or absolute magnitude of variance in a time series at a particular period or frequency, as a function of that period or frequency (**Figure 2**), and provides a ‘frequency domain’ summarization of climate variability. Typically, variance spectra are plotted on log scales to accommodate the large range of timescales discussed, and the general tendency is for the total variance of longer-term variations of the climate system (e.g., glacial–interglacial variations) to be orders-of-magnitude larger than shorter-term variations (e.g., interannual variations). Mitchell (1976) drew a schematic variance spectrum for climate-system variations that covered timescales ranging from the age of Earth (geological timescales) down to hours (meteorological timescales). Based on analyses of series that represented parts of this time range (Hays et al., 1976; Kutzbach and Bryson, 1974), as well as considerable intuition, Mitchell’s spectrum was innovative in its attempt at presenting a general conceptual model that organized a large body of insight into how the climate system operates. Subsequent workers have progressively refined Mitchell’s schematic spectrum (Saltzman, 2002), or developed data-derived spectra for parts of the record (Shackleton and Imbrie, 1990; see also Wunsch, 2003).

Figure 2 is based on Mitchell’s spectrum, supplemented by material from the descendent papers. It differs somewhat from Mitchell’s in that the spectrum here was drawn to display an overall slope of -2 , that is, the ‘power-law’ spectrum of a simple random walk, in order to depict the long-run ‘nonstationarity’ of the climate system (Wunsch, 2003). Superimposed on this general background variability, which dominates the spectrum, are ‘peaks’ that represent the concentrations of variability associated with external drivers or internal autovariations. Some of these, like those associated with the annual cycle, ENSO, and the orbital elements, have underlying physical mechanisms that are truly cyclical (and hence are drawn with sharper peaks), while others, like the Holocene or tectonic ‘cycles’ do not. These are commonly referred to as ‘cycles’ but at best are only quasi-, or apparently, periodic. They are drawn here with broader peaks or ‘shoulders’ in the spectrum.

The first-order pattern on the schematic spectrum is the great increase in variance that occurs with increasing period, with second-order peaks of lower importance superimposed on this overall pattern. Comparisons can be made between the peaks and overall background variance at particular timescales. For example, the variations in global ice volume at a period of 100 ka that characterize the past million years (**Figure 1(b)**) have similar variance as the variations in the general mean state of climate that take place on 5–10 My timescales (**Figure 1(a)**). The tectonic ‘cycle’ peaks represent climate-system variability on timescales of 400 My (‘Wilson cycles’ of continental

Figure 1 Some representative paleoclimatic time series and examples of typical kinds of climatic variations: (a) composite global oxygen-isotope record for the Cenozoic (Zachos et al., 2001); (b) stacked global oxygen-isotope record (Lisiecki and Raymo, 2005); (c) oxygen-isotopic variations from the GISP 2 Greenland ice-core record (Stuiver et al., 1997); (d) Dongge Cave speleothem oxygen-isotope record (Wang et al., 2005); (e) reconstruction of Northern Hemisphere temperature anomalies over the past two millennia (Moberg et al., 2005), along with the observational record of the past century (Hansen et al., 2006). Typical kinds of climatic variations (Table 1) are illustrated as follows: T, trend; S, step; O, oscillation; F, fluctuation; and E, event.

Figure 2 Schematic variance spectrum of climatic variations.

assembly and reassembly; Wilson, 1966), 200 My (variations among Phanerozoic climate modes, Frakes et al., 1992), 62 My (fossil diversity variations; Rhode and Muller, 2005), and steps in the Cenozoic oxygen-isotope record that are approximately 10 My apart (Figure 1(a); Zachos et al., 2001). Orbital cycles include the 400, 100, 41, and 23 (plus 19) ka climate (ice-volume and monsoon-strength) variations related to periodic insolation variations. A broad spectral peak is shown for Dansgaard-Oeschger cycles (Figure 1(c)), although these variations are not strictly periodic (Alley et al., 2001). Holocene timescale variations are shown schematically as broad peaks corresponding to millennial, centennial, and decadal-scale variability. Although often described as ‘cycles’ (e.g., ‘1500-year Bond cycles,’ see Bond et al., 2001), the periodicity of the variations is not sufficiently regular for them to be considered truly cyclical. Similarly, ENSO-related variations are only quasi-periodic and contribute a broad peak to the variance spectrum, while the truly periodic annual cycle contributes a very narrow peak. (The width of the annual-cycle peak on Figure 2 is exaggerated for visibility.)

The overall impression from either the schematic spectra, or from the time series themselves, is that (with the exception of the annual cycle) the variations of the climate system are almost completely stochastic. Even the variations arising from external controls that are nearly deterministic (such as the variations of the orbital elements that generate ice-volume variations) or from internal variations with physical generating mechanisms that are oscillatory in nature (such as ENSO) have considerable unpredictable ‘noise’ components. Variability of climate could thus be described as occurring over all timescales, with variability greatly increasing as scale increases, but with concentrations of variance at some preferred timescales.

Changing Variability

A variance spectrum, such as that in Figure 2, displays the ‘global’ level of variance at specific periods, and consequently masks the ‘local’ (over time) changes in the importance of

variability at particular periods, which is evident in many climatic time series (Figure 1(b) and (c)). One device for illustrating such changes in variability or in the relative importance of variations on different timescales is the evolutionary spectrum, also known as a moving-window spectrum. Evolutionary spectra constructed using the wavelet procedure (Torrence and Compo, 1998) for the stacked marine oxygen-isotope record (Lisiecki and Raymo, 2005) and the bidecadal GISP 2 oxygen-isotope record (Stuiver et al., 1997) are shown in Figure 3. The plots show ‘scaled power’ or variance plotted as a function of period of variation and time.

The evolutionary spectrum for the stacked global oxygen-isotope record clearly shows the increase in importance in 41-ka variations beginning around 2.65 Ma and in 100-ka variations beginning around 1 Ma, but it also shows that variations at these timescales were important during previous times. The 41-ka variations are evident throughout the record and variations at the other orbital periods can be seen to vary in their relative importance. The evolutionary spectrum for the GISP 2 oxygen-isotope data (Figure 3) clearly shows the importance of millennial-scale Dansgaard-Oeschger variations prior to the Holocene and also illustrates the changing period of those variations. From the beginning of the record plotted here until around 42 000 years BP, variance is concentrated at periods around 5000 years, and shifts to progressively shorter periods from then until 30 000 years BP. During MIS 2 and during the Holocene, there is little concentration of variance at any period shorter than 5000 years. The high variance at the longest timescales (e.g., 10 000 years and longer), although not demonstrably significant due to record-length constraints, reflects the important underlying signature of orbital-timescale variations in this record.

Changes in the relative importance of variations on different timescales are the rule in climatic time series, appearing in a variety of differing contexts (Overpeck and Webb, 2000). Explanation of the changes in variability of climatic time series presents a potentially greater challenge than explanation of changes in the mean, but must be accepted owing to the great impact climate variability has on human activity.

Figure 3 Evolutionary spectra calculated using the wavelet method (Torrence and Compo, 1998; <http://atoc.colorado.edu/research/wavelets/>) for the stacked global oxygen-isotope record (Lisiecki and Raymo, 2005) and oxygen-isotopic variations from the GISP 2 Greenland ice-core record (Stuiver et al., 1997). Gray areas indicate the regions outside of the 'cone of influence' where record-length considerations make the estimates less robust.

Spurious Periodicity

As mentioned earlier, the use of the variance spectrum to characterize climate variability, when coupled with the general tendency of climatic time series to wander back and forth, naturally directs attention toward explanations of climatic variability that invoke controls or mechanisms that are cyclic in nature. However, it is likely that the nature of the variability plus some commonly applied data-analytical tools yield series that merely appear periodic when they intrinsically are not so.

Figure 4 shows three examples of time series that feature quasiperiodic variations, each generated by filtering or transforming a series of normally distributed random numbers in an intrinsically aperiodic way. In each figure, the random numbers are plotted in gray in the background on an arbitrary scale, and the generated series in black.

Figure 4(a) shows a time series generated by the second-order autoregressive model:

$$z_t = \phi_1 z_{t-1} + \phi_2 z_{t-2} + a_t$$

where $\phi_1 = 1.32$ and $\phi_2 = -0.66$, and a_t is a normally distributed or Gaussian white-noise time series. This is the 'classical' second-order autoregressive or AR(2) model that describes Wolfer's sunspot series (Box and Jenkins, 1976), and autoregressive models have generally found wide application in representing time series with both short- and long-run memory. The resulting series clearly shows a rough 10 time-step oscillation, and further displays a change in amplitude and regularity of this oscillation mid-way through the series, which would probably provoke comment if this were a real paleoclimatic time series.

Figure 4(b) shows a linearly detrended time series, $\tilde{x}_t$, where

$$\tilde{x} = x_t - b_0 - b_1 t$$

and x_t is an integrated autoregressive process

$$x_t = x_{t-1} + y_t$$

$$y_t = \phi_1 y_{t-1} + a_t$$

Figure 4 Some illustrations of spurious periodicity. Series plotted in pale blue are the white-noise time series used to generate the simulations in dark blue: (a) a second-order autoregressive process (AR(2)); (b) an improperly detrended integrated autoregressive model; and (c) running mean-filtered white noise (thick blue line represents the output from a 15-term running mean, thin blue line from a 10-term running mean of the data represented by the thick blue line).

with $\phi_1 = 0.8$ and a_t a normally distributed white-noise time series. The series x_t is an example of a ‘difference-stationary’ time series, or one in which the first differences of the series, $y_t = x_t - x_{t-1}$, are stationary or vary in a stable fashion over time. If treated instead as a ‘trend stationary’ time series, spurious periodicities can appear in the residual series, $\tilde{x}$, when x_t is linearly detrended (Nelson and Kang, 1981). The example series shows a broad cycle with a wavelength close to the record length and also shows lower-amplitude, higher-frequency variation, with a period around 20 time steps. Again, although generated by an aperiodic process, the resulting series could be viewed as being cyclic in nature. Paleoclimatic time series are frequently detrended as part of preliminary steps in data analysis.

Probably the most frequently applied method for generating apparently periodic variations in a time series when none really exist is illustrated in Figure 4(c), which demonstrates the Slutsky–Yule effect (von Storch and Zwiers, 2001). The dashed

line in Figure 4(c) is the result of applying a 15-term running mean to a white-noise time series:

$$y^t = \frac{1}{n} \sum_{i=1}^n w_i a_{t-i}$$

where $n = 15$, $w_1 = w_2 = \dots = w_n = 1$, and a_t is the white-noise time series. The solid line is simply the y_t ’s further smoothed by a 10-term running mean. The resulting series are clearly periodic and would likely be described or explained as ‘cyclic’ if they were real. Slutsky’s theorem (Jenkins and Watts, 1968) shows that by repeated application of summing (as in the running mean) or differencing filters, white noise can be reduced to a sine wave. In practice, smoothing like that done by the running mean can occur naturally in paleoclimatic records that integrate environmental conditions over time, but usually the smoothing occurs during data analysis.

All three series appear periodic yet are generated by relatively simple processes, without invoking any mechanism that could be intrinsically cyclical or periodic in nature. Because there are multiple ways of generating series with apparent periodicity, some of which are related directly to commonly applied data-analysis procedures, a relatively high standard should exist for declaring a particular series as cyclical and searching for explanations within the class of oscillatory or cyclical physical mechanisms.

Characteristic Kinds of Climate Variability

A Taxonomy of Typical Features in Climatic Time Series

An alternative ‘time domain’ approach for describing the nature of climate variability, other than that provided by the variance spectrum, is to describe the kinds of typical features or characteristic variations that recur in many climate climatic time series across a range of different timescales. There are a relatively small number of different kinds of variations that climatic time series display.

Table 1 gives examples of such typical variations, the levels in the climate system hierarchy that contain the controls of the variation, and those that are involved in the response. The table also indicates the predictability and reversibility of the individual kinds of variations. Climate variations are (a) predictable (P), if the timing and amplitude of the variations can be specified; (b) expectable (E), if either the timing or amplitude can be specified, but not both; or (c) unpredictable (U), if neither the timing nor amplitude of the variation can be specified. Variations are reversible (R), if the climate returns to a previous general mean state following the occurrence of the variation, or not reversible (N), if the climate does not return. The predictability and reversibility has implications for the biotic response to climate variations: Migration is the principal response to predictable and reversible climatic variations, while evolution (and extinction) is that for unpredictable and irreversible variations (Bartlein and Prentice, 1989; and Bennett, 1997). The table also shows the relative importance of trend, systematic (or periodic), and irregular components.

Table 1 Characteristic features or kinds of climatic variations

Kinds of variations	Examples	Levels in hierarchy ^A		Predictability/ reversibility ^B		Components of temporal variations ^C		
		Control	Response	Predict.	Reverse	Trend	System.	Irreg.
Trends								
Era-long	Cenozoic global cooling and glacierization	E	G–L	E	N	H	L	L
Glacial–interglacial	Last deglaciation	E,G	H–L	P	R	H	L	L
Multi-millennial	Late Holocene summer cooling in northern mid-latitudes	G–C	R–L	E	R	L	L	H
Century-long	Global warming	G–C	R–L	E	R	L	L	H
Steps								
Inter-epoch	Onset of N. Hemisphere glaciation (~2.65 Ma)	E	G–L	U	N	H	L	L
Millennial	5.5 ka African Monsoon collapse	C	R–L	E	R	H	L	L
Oscillations								
Periodic (orbital)	Ice sheet growth and decay, monsoon strengthening/weakening	E	G–L	P	R	L	H	L
Changing-periodic (orbital)	Strengthening of 100-ka cycle in past million years	E	G–L	U	N	L	H	L
Quasiperiodic (suborbital)	Dansgaard–Oeschger ‘cycles’ (75–10 ka)	E,G	H–L	E	R	L	M	H
Interannual (10 ⁰ –10 ¹ yrs)	ENSO variations, decadal-scale climate anomalies	H,C	R–L	E	R	L	M	M
Fluctuations								
Holocene (10 ³ –10 ⁴ years)	Holocene temperature and precipitation variations	G,H	C–L	E	R	M	L	H
Submillennial (10 ³ –10 ⁴ years)	Medieval warm period/Little Ice Age variations	G–C	R–L	E	R	L	L	H
Interannual (10 ⁰ –10 ¹ years)	Aperiodic interannual climate variations	H,C	R–L	E	R	L	L	H
Events								
Excursions (10 ⁵ –10 ⁶ years)	Late Paleocene Thermal Maximum	G	C–L	U	R	H	L	L
Climate reversals (10 ² –10 ⁴ years)	Younger Dryas climate reversal (~12.8–11.6 ka)	G–C	R–L	E	R	H	L	L
“Abrupt changes” (10 ¹ –10 ² years)	8.2 ka event	G–C	R–L	E	R	L	L	H
Interannual (10 ⁰ –10 ¹ years)	Pinatubo eruption global cooling	G	R–L	E	R	L	L	H

^aLevels in climate system hierarchy (E, external; G, global; H, hemispheric; C, continental; R, regional; L, local) controlling (Control) characteristic features of climatic variation or responding (Response) to them.

^bPredictability (Predict.) and reversibility (Reverse) of characteristic features of climatic variations: P, feature is predictable at the temporal or spatial scale indicated; E, feature is expectable, but not specifically predictable; U, feature is unpredictable.

^cRelative amplitude (H, high; M, medium; L, low) of components of temporal variations (Trend, Systematic (periodic or otherwise predictable), Irregular).

Trends

Trends are progressive increases or decreases in the levels of a particular climate variable; they appear in paleoclimatic variations on all timescales, but are particularly evident at certain scales. At the longest timescales displayed in [Figure 1\(a\)](#), cooling during the Cenozoic is evident in the general change in oxygen-isotopic ratios toward heavier values (i.e., toward cooler oceans, more ice). This trend is probably driven by the external controls of the climate system, with all the lower levels in the hierarchy responding. The general trend is broken, of course, by local increases in global temperature (as in the Eocene, ~50 Ma), and by locally more rapid decreases, but the overall impression when viewing this series is of a progressive

movement toward cooler conditions. The cooling trend is therefore expected once underway (but its particular amplitude is not predictable), nonreversing overall, and dominated by the long-term changes ([Table 1](#)). [Figure 1\(b\)](#), oxygen-isotope data for the past 5 My, also shows a generalized trend, which is the same climatic change as the more rapid decrease in global temperatures that is evident in the last part of Series A. On a shorter timescale ([Figure 2\(c\)](#)), the general transition between the Last Glacial Maximum (about 21000 years ago) and the present can be viewed as a trend (predictable and reversible), although broken by the Younger Dryas climate reversal (between 12.8 and 11.6 ka). During the Holocene ([Figure 1\(d\)](#)), many locations in the northern mid-latitudes experienced a cooling trend

in summer, or in the northern tropics and subtropics, a reduction in the strength of the monsoon. Finally, during the last century (Figure 1(d)), the global mean temperature, as well as that at individual stations, has generally increased.

Steps

Steps are the abrupt (relative to the timescale of variations under consideration) transitions from one level to another, and appear on many different timescales. Notable examples of steps in the representative series include the unpredictable and nonreversing interepoch decreases in global temperature during the Cenozoic (Figure 1(a)). Similarly, abrupt steps occur at the beginning and end of the Younger Dryas climate reversal and at the terminations of the 'Dansgaard-Oeschger' cycles during the interval between 60 and 20 ka (Figure 1(c)). These steps are expected, but not predictable, and have little irregular variation superimposed on the transition from one level to another.

Oscillations

Oscillations are either periodic or quasiperiodic variations about a stationary or slowly changing level and are one of the more prominent features of paleoclimatic time series. Oscillations dominate the glacial-interglacial variations in global temperature, and the variations in the continent-ocean temperature contrast that govern the monsoons, each generated by the periodic variations of the Earth's orbital elements (Figure 1(b)) (Imbrie et al., 1984; Prell and Kutzbach, 1992). Consequently, these variations are highly predictable and systematic. One important characteristic of the oxygen-isotope variations apparent in Figure 1(b) is the change in the relative importance of the different periodic components. Prior to 1 Ma, the 41-ka cycle is relatively more important, whereas thereafter, the 100-ka cycle becomes more prominent. These changes in periodicity seem inherently unpredictable and nonreversing. Quasiperiodic variations (i.e., variations that are less regular than the strictly periodic ones of the stacked global record) appear at 'suborbital' timescales, as in the aforementioned Dansgaard-Oeschger cycles. Interannual climate variations such as those constituting the El Niño/Southern Oscillation (ENSO) variations (Diaz and Markgraf, 2000) have also been described as quasiperiodic. Although systematic variation is apparent in these series, they are only expected owing to the absence of strict periodicity.

Fluctuations

Fluctuations are aperiodic variations of climate appearing at all timescales, but they tend to be more evident at shorter timescales. Variations in Northern Hemisphere temperature are dominated by interannual fluctuations, with decadal- and centennial-scale variations of less importance, with the exception of the past century. Fluctuations are expected, but not specifically predictable features in individual time series, and are distinguished from steps by their inherent reversibility.

Events

Events are similar in nature to steps, but are variations that return rapidly (relative to the timescale of variations under consideration) to a previous state, and hence are always reversible and distinct from steps. Examples of events are the late Paleocene Thermal Maximum (the distinct oxygen-isotope

peak at 55 Ma visible in Figure 1(a)), the Younger Dryas climate reversal, and 8.2-ka 'event' evident in the GISP 2 record (Figure 1(c)). What constitutes an event, as opposed to one of many fluctuations in a record is subjective, but generally events are both large and isolated, relative to nearby or background fluctuations.

At any given time or place, the prevailing climate is the product of the superimposition of all these features as they occur across all the different timescales. The efficacy of a particular feature in producing a response in some biotic or abiotic environment that is encoded in the paleoenvironmental record probably depends on the amplitude of the associated climatic variation and its duration, the number of features superimposed, the tendency for a particular variation to be predictable or reversible, and also on the existence of intrinsic thresholds.

Summary

The mean state of climate (or of the climate system) varies considerably, and these variations are expressed across a range of timescales. Moreover, the variability of the mean-state variations also varies over time. Despite this situation, there is considerable structure to the variability of climate. When viewed in the frequency domain, most of the variability of climate is related to the general increase in variance with increasing timescale, but there are several preferred timescales of variability related to the influence of external controls of climate and to internal mechanisms that generate quasiperiodic variations. The preferred timescales or periods related to external controls are those of 10^6 years and longer, which are related to tectonic controls, 10^4 – 10^6 years related to variations of the Earth's orbit, and the annual cycle, while those related to interval variations occur on interannual-to-millennial scales.

When viewed in the time domain, a small number of characteristic kinds of variation can be seen that recur across the full range of timescales. These typical variations include trends, steps, oscillations, fluctuations and events, and the superimposition of these generate climatic time series that show little stasis, or intervals of low variability over time.

Modern Analog Approaches in Paleoclimatology

Introduction

Quaternary paleoclimatic reconstructions of the last 21 000 years provide a long and detailed perspective on climatic variability, which in turn, enables a better understanding of the causes and mechanisms of climatic change (Bartlein et al., 1998; COHMAP Members, 1988). Synoptic climatological analyses provide useful information for understanding these causes and mechanisms as they relate to paleoclimatic evidence within a particular region (Barry and Perry, 1973; Barry, 1981; Hirschboeck et al., 1996; Serreze and Barry, 2005). Prior to the mid-1970s, most analyses of synoptic climatology of the past relied on the modern synoptic analog approach of past climates because this was the primary approach for reconstructing past atmospheric circulation. The modern analog approach is based on the uniformitarianism principle (Barry and Perry, 1973). It assumes that the range of modern conditions contains extreme events that may have been more frequent in the past and that the processes work in the same way during both times. However, a primary drawback to the modern analog approach is that no perfect analog for past climates prior to instrumental records exists, especially for longer Quaternary timescales, because external climatic controls such as ice sheet size, incoming insolation, and carbon dioxide concentrations differed dramatically when compared with today's conditions (e.g., Mitchell, 1990). The advent of GCM (general circulation model) simulations of past climates during the 1970s became a much more popular method of examining synoptic paleoclimatic patterns, as they provide a theoretical basis of how the climate system may have operated in the past.

However, GCMs have limitations in spatial resolution (usually about 1.5° longitude $\times$ 1.5° latitude of resolution) and in how they portray topography (Kohfeld and Harrison, 2000; McGuffie and Henderson-Sellers, 2005). RCMs (regional climate models) provide better resolution and more accurate topography but still greatly amplify it in some areas (e.g., Diffenbaugh and Sloan, 2004; Hostetler et al., 1994, 2000). Furthermore, GCMs have made some advances in simulating details on decadal- and century-scale climatic changes during the last 1000 years and matching results with proxy data (e.g., Seager et al., 2009), but this has not been the case for RCMs in the last 600 years. Modern synoptic analogs can provide greater spatial resolution as a result of copious station networks, and they can be applied much more readily to specific paleoclimate problems than previous applications of climate modeling.

Unlike the goals of most studies prior to the 1970s, the goal of modern synoptic analogs today is not simply to reconstruct past atmospheric circulation, but instead to provide explanations on how processes in the atmospheric portion of the climate system work in order to explain paleoclimatic variations of the past. Recent development of reanalysis datasets

such as the NCEP-NCAR Global Reanalysis (Kalnay et al., 1995; Kistler et al., 2001), North American Regional Reanalysis (Mesinger et al., 2006), and ECMWF-European Reanalysis (Uppala et al., 2005) provide new data resources for modern synoptic analog approaches. The reanalyzed data represent output from three-dimensional forecasting models initialized with observational data and interpolated onto a grid of similar global or regional resolution as GCMs and RCMs. Though simulated, reanalysis data are constrained (approximately every 6 h) by actual observations and therefore are regarded as a physically consistent depiction of past meteorological conditions. Output from such reanalyzed datasets often includes a broad suite of synoptic and dynamical meteorological fields (e.g., energy and water balance, atmospheric circulation), which can be used for modern synoptic analogs to understand climatic mechanisms associated with paleoclimate reconstructions (Shinker et al., 2006).

Modern synoptic analogs are obviously not perfect analogs but serve as partial analogs, or 'component' or 'process analogs' (Crowley, 1993; Webb et al., 1993). This article reviews the literature of modern synoptic analogs for paleoclimatic interpretation, discussing studies that involve longer (late Pleistocene to mid-Holocene) and shorter (AD 1000 to the present) timescales. It also discusses the drawbacks and assumptions of the analog approach and the changing nature of methodologies, and offers some suggestions for further research. Discussion is divided into two main parts: environment-to-circulation and circulation-to-environment approaches. These two approaches have been chosen because they represent the primary approaches in conventional synoptic climatological research (Barry and Carleton, 2001; Yarnal, 1993; Yarnal et al., 2001).

Environment-to-Circulation Approaches

The environment-to-circulation approach deals first with specifying certain conditions of the surface climate of interest in a particular area (e.g., extreme heavy rainfall), based on variations of modern instrumental data that are believed to resemble a particular climate in the past. The specification of these conditions is often selected according to a pattern of climatic anomalies as represented by a network of paleoclimatic proxy data. Based on the similar specified surface climate in the modern instrumental record, which represents a particular climatic extreme that may cover a month or a period of years, the corresponding atmospheric circulation is then examined in order to find the circulation patterns that may have occurred in the past.

Studies at Regional to Hemispheric Scales

One of the first systematic studies utilizing this approach for examining past climates was done by Simpson (1934), who constructed a hemispheric map of sea-level pressure for the late

Pleistocene, based on the distribution of abnormally extensive snow and ice. This approach was expanded by [Lamb \(1964\)](#), who constructed maps of winter and summer sea-level pressure for the late Pleistocene but used a more extensive dataset of snow and ice covering the period from 1920 to 1940. [Mather \(1954\)](#) also conducted a similar approach, using anomalies of sea-level pressure for the period 1931–40 as representative of full glacial climate because of generally lower mean annual temperatures in the Northern Hemisphere during this decade. As boundary conditions during the Last Glacial Maximum were dramatically different from what they are today, involving a large ice sheet at higher latitudes, lower sea-surface temperatures, lower concentrations of carbon dioxide, and different forcing conditions that involve the thermohaline circulation and sea ice ([COHMAP Members, 1988](#); [Otto-Bliesner et al., 2007](#)), the assumption that the present is a key to the past is invalid at the hemispheric as well as at the continental scale. For example, Mather's analysis implied that a northward and eastward shift of the Aleutian low would create drier conditions relative to today throughout the western United States, and this is inconsistent with implications from both proxy data and GCM simulations ([Otto-Bliesner et al., 2006](#); [Thompson et al., 1993](#)). Furthermore, the dating control as well as spatial coverage of proxy data used by Mather at the hemispheric scale is inadequate for conducting a detailed analog analysis.

[Barry \(1983\)](#), however, suggested that modern synoptic analogs may provide useful information regarding anomaly patterns of atmospheric circulation of past climates below the continental scale, given that sufficient proxy data are available for providing detailed surface conditions. [Nicholson \(1978, 1994\)](#) illustrated that this holds true at the spatial scale of central and northern Africa. She examined anomalies of precipitation from the nineteenth and twentieth century, comparing modern and historical composite anomalies with anomalies of the periods 20–15 and 10 ka reconstructed from proxy data. Patterns of the widespread reduced rainfall of the 1970s correspond to the climate anomalies of 20–15 ka, and the generally wet pattern for 1870–95 fits fairly well with that at 10 ka. Nicholson did not examine circulation data, but suggested that rainfall changes appear to be large scale in nature and that the characteristics of circulation associated with monsoonal flow in the present are similar to those in the past. The paleoclimatic and some twentieth century anomaly maps also show, interestingly, some opposite anomaly signs, particularly in East Africa and the western African tropics. Nicholson suggested that Saharan depressions may cause some variations that exhibit heterogeneous patterns.

[Edwards et al. \(2001\)](#) used a modern analog approach to examine how specific atmospheric configurations could have produced regional patterns of surface temperature and effective moisture during 14 000 cal year BP in interior Eastern Alaska seen in paleoclimate records but not captured by GCM simulations. They identified circulation anomalies during July 1964 as modern analogs to the cold and dry conditions that likely occurred in eastern Beringia until 14 000 cal year BP. They also constructed composites based on conditions in the instrumental record indicating a strong ridge leading to dry easterly flow and warm conditions as analogs to the early Holocene climate. Results were found to be consistent with proxy data networks (e.g., [Anderson et al., 2005](#)). [Edwards et al. \(2001\)](#) also

proposed a cold/wet pattern featuring enhancement of westerly flow into Alaska as a partial analog for the cold periods of the Little Ice Age. [Kokorowski et al. \(2008\)](#) described several synoptic controls associated with the position and strength of the Aleutian low and Siberian high leading to heterogeneous responses of Beringian climate during the Younger Dryas chronozone that help explain the contrasts between western Beringia and eastern Beringia, as well as topoclimatic variations within the region. However, their synoptic inferences were not based on any modern analog, as they believed that in this situation, an ideal close one could not be found.

Several scholars have utilized synoptic classification techniques commonly used in synoptic climatology in order to conduct their analog analyses. [Brinkmann and Barry \(1972\)](#) constructed 700-mb composite maps along with their associated precipitation, and temperature patterns, based on six extreme snowy winters and six extreme cool summers to determine the circulation patterns that explain the response of some proxy data in Keewatin and Labrador-Ungava, Canada. They assumed that the modern synoptic analogs may represent conditions conducive to glacial inception; with such modern conditions perhaps representative of conditions existing at least through the Holocene (cf. [Kaufman et al., 2004](#)). The 700-mb composite map for snowy winters shows a weaker-than-normal and westward migration of a trough in central Canada. Temperature anomalies for both Keewatin and Labrador-Ungava are positive. The 700-mb composite map for cool summers indicates a trough centered over eastern Hudson Bay, with dry conditions in Keewatin and wet conditions in Labrador-Ungava. The modern synoptic analogs suggest that vegetation changes at both locations would covary in response to summer temperature, but vegetation at both locations may respond differently as compared with one another in terms of precipitation.

[Antonsson et al. \(2008\)](#) used a synoptic classification scheme to identify groups of daily synoptic patterns to explain dry and warm mid-Holocene summer conditions in central Sweden. Their classification was based on daily mean sea-level pressure data from 1850 to 2003 using the Lamb–Jenkinson object classification for atmospheric circulation (also see [Lamb, 1950](#); [Jenkinson and Collison, 1977](#); [Chen and Li, 2004](#)). The dry and warm mid-Holocene summer climate in central Scandinavia likely occurred as a result of dominant summer anticyclonic circulation causing persistent blocking highs. Comparison of the reconstructed climate with simulations of modeled climate indicated that the modeled climate (predominantly driven by large-scale insolation patterns) underestimated the dry and warm period seen in the reconstruction; thus by assessing smaller-scale circulation analogs, [Antonsson et al. \(2008\)](#) were able to provide an alternative explanation for the regional summer climate patterns during the mid-Holocene.

[Diaz and Andrews \(1982\)](#) searched for a circulation regime for the warm mid-Holocene in northern North America by examining modern July temperature patterns derived from a principal component analysis and comparing the major modes of variability with patterns derived from a principal component analysis of fossil pollen data. [Diaz and Andrews \(1982\)](#) implied that the 700-mb circulation patterns for July 1961 and July 1972 are similar to the most important pattern portrayed by the pollen data, with a distinct ridge over mid-Canada, and

Figure 1 Distribution of the seasonal precipitation maximum. Refer to [Mock \(1996\)](#) regarding the timeframe of climatic normals, which differ slightly with respect to different observational networks.

that such patterns may prove useful for comparing with GCM simulations. The use of the first few principal component analysis and the somewhat spatially sparse pollen network, however, prevent the analysis of possible patterns of spatial heterogeneity of climate at smaller spatial scales.

Only one study, by [Sanchez and Kutzbach \(1974\)](#), was found to deal with the application of an environment-to-circulation approach at the regional-to-continental scale for shorter timescales. The authors examined differences of annual precipitation and temperature for the period 1961–70 covering parts of the southern United States, Central America, and part of South America in order to study spatial climatic variations that occurred during the Little Ice Age. They chose 1961–70 because it was characterized with widespread negative temperature anomalies throughout most of the American tropics. Widespread decreases of precipitation were also evident, and accompanying circulation changes indicated a southward displacement of the general circulation. Proxy data for comparison, unfortunately, is extremely sparse, and no clear consensus currently exists to conclude that the American tropics were clearly characterized by widespread colder temperatures during the Little Ice Age.

Studies at Local to Regional Scales

Surface climate responds to a hierarchy of climatic controls, involving larger-scale controls such as the polar jet stream and

smaller-scale controls such as topography ([Barry, 1970, 1982; Mock, 1996; Shinker, 2010](#)). As one analyzes climatic controls below the regional scale, more smaller-scale controls become superimposed over larger ones, creating a multitude of unique climatic regimes that are consistent with a particular set of larger-scale controls. Within some regions at smaller spatial scales, climates may be largely topographically controlled, thus the modern climate shares some characteristics of climatic controls that may have operated in the past. Spatial heterogeneity of precipitation seasonality is demonstrated by their spatial patterns over the United States and adjacent areas ([Figures 1 and 2](#)). Homogeneous precipitation maxima are apparent, such as the progression of winter precipitation maxima over the far Western United States by mid-latitude cyclones from the North Pacific, the extent of the summer precipitation from monsoonal processes in the Southwest, and the spring precipitation maxima over the Southeast United States from spring cyclogenesis ([Mojzisek and Mock, 2009](#)) ([Figure 1](#)). Heterogeneous seasonality patterns are most apparent in regions of diverse terrain such as the Rocky Mountains ([Mock, 1996; Shinker, 2010; Shinker and Bartlein, 2010](#)) and some places along water bodies that include the Great Lakes. Interestingly, seasonal precipitation minima over the United States generally exhibit more homogeneous patterns ([Figure 2](#)), which need to be assessed differently than precipitation maxima when also analyzing paleoclimate patterns. Illustrating several examples, winter precipitation minima are evident

Figure 2 Distribution of the seasonal precipitation minimum. Refer to [Mock \(1996\)](#) regarding the timeframe of climatic normals, which differ slightly with respect to different observational networks.

over a large part of the eastern United States due to the absence of convection, a May–June minima over the Southwest, indicative of the circulation regime prior to monsoon onset, and summer minima over the West due to dominance of the Pacific subtropical high.

Modern synoptic analogs can provide valuable information regarding heterogeneous surface climatic responses to specific regional synoptic patterns in areas characterized by complex terrain. For example, [Mock and Brunelle-Daines \(1999\)](#) used a modern analog approach selecting August 1955 as a summer climate analog to describe the likely dominant circulation control leading to widespread drought over parts of the West and mid-continent, and enhanced monsoonal flow in the southwestern United States interpreted from proxy records during 6 ka. Modern synoptic analogs can also be conducted for localized subregions as well as for individual locations, but caution must be exercised in the selection of modern extremes in order to compare them with past climates. For example, abnormally wet conditions in the Great Basin of the western United States can arise from three different synoptic patterns: winter mid-latitude cyclones from the Pacific, cyclogenesis in the northeastern Great Basin, and monsoonal moisture from the Gulf of California ([Kay, 1982](#)). Thus, the investigator must know, specifically, what types of synoptic processes are of interest when formulating an environment-to-circulation analog approach.

[Streten \(1974\)](#) attempted to find a synoptic pattern that explained the dry and warm summers in interior Alaska that was believed to be representative of the last glaciation. From temperature and precipitation data, he examined 700-mb circulation during such modern extremes and noted that they correspond with a strong upper ridge over the region, with a deep low pressure system to the west. [Bowling \(1979\)](#) conducted a similar approach, but based the surface conditions from biological and geomorphological evidence, which showed wetter-than-normal conditions along the southern Alaska coast, and drier- and warmer-than-normal conditions inland. She implied that the winter circulation of 1976–77, characterized by increased southwesterly flow from the Gulf of Alaska, would be a synoptic pattern that explains the contrast of climatic anomalies along the coast and inland. It is similar to the pattern as implied by [Streten \(1974\)](#), thus such a pattern may have been more persistent during the Last Glacial Maximum during the course of the annual cycle.

Some analog studies specified a different type of surface environment other than temperature and precipitation to directly study synoptic climatic relationships with particular surface processes that may have operated more frequently in the past. [Enzel et al. \(1989, 1990\)](#) examined modern winter sea-level circulation patterns that may explain the existence of ephemeral lakes in the Mojave Desert, California. They constructed a sea-level composite-anomaly map on the basis of

8 months with lake-building flood events. Their map shows anomalous southwesterly flow with enhanced advection of warm, moist Pacific air into the region, associated with a deep cutoff low offshore and a blocking high in the Gulf of Alaska. Enzel et al. (1989, 1990) acknowledged that anomalously warm sea-surface temperatures may have affected circulation anomalies in the composite map, but implied that this general pattern was dominant prior to 9 ka and perhaps as far back as 18 ka. Ely et al. (1993) and Ely (1997) also examined modern flood analogs in Arizona and Utah. These studies classified three main types of flood analogs: the first caused by winter North Pacific frontal storms, the second caused by late-summer and fall storms associated with tropical storms and cutoff lows, and the third caused by localized summer convective thunderstorms. Composite maps of 700-mb heights were constructed for each analog type and compared to a 5000-year chronology of paleoflood events on the basis of flood deposits. Results from these studies suggest that long-term flood variability is associated with changes in large-scale circulation and cool, moist climate, including conditions involved in ENSO events, with flooding activity being the highest around 4800–3600 BP, around 1000 BP, and after 500 BP.

Van Heuklon (1977) used a similar analog approach to explain loess transport in Illinois during the last major Ice Age. He searched for daily events that were characterized by excessive dust transport for the region and then examined upper-level weather maps. Using weather maps from 13–15 October 1976, he implied that Alberta lows, coming from a northwesterly direction, may account for some fine-grained material to be transported in the region.

Several researchers have used an environment-to-circulation approach for studying atmospheric circulation to explain surface climate within the annual-to-historical (Little Ice Age) timescales. These analog approaches looked for a few ideal modern extreme events that best fit past climate. Bryson et al. (1974) examined precipitation patterns and associated circulation of the eastern Mediterranean for January 1955 and suggested that the occurrence of similar patterns may explain drought conditions in Mycenaean Greece around AD 1200. They also noted that the climate anomalies for January 1955 outside of southern Greece agree with climatic implications from pollen and historical evidence from the surrounding region. Weiss (1982) derived similar conclusions using a more dense station network and PDSI (Palmer Drought Severity Index) data, suggesting that January 1972 is also an accurate analog.

Newell (1992) examined modern synoptic analogs that correspond to summer 1816 temperature patterns in the Labrador Sea. He implied that months characterized with deep-low-pressure centers in the Labrador Sea, particularly June 1978 and June 1986, cause increased northwesterly winds and colder temperatures over the nearby land areas. Temperature anomalies for June 1978 and June 1986 were not as large as those for the summer of 1816, but Newell argued that the synoptic pattern for 1816 was most likely more intense. Stine (1994) implied that winter circulation of several dry years in the 1930s and for the winter of 1976–77 over California was more predominant during the Medieval Warm Period. He suggested that a contracted circumpolar vortex occurred in the past, but the winter synoptic analogs do not offer conclusive

proof, and all paleoclimatic evidence in mid-latitudes do not indicate widespread dryness (Hughes and Diaz, 1994). Mock (1991) specified patterns of summer freezing temperatures and heterogeneous but generally dry precipitation anomalies in the eastern Great Basin and adjacent Rocky Mountains during climatic extremes, and he used the associated circulation patterns from these extremes to study circulation patterns that may have prevailed during the summer of 1849. The analysis of the summer weather of 1849 was further studied by Blair and Rannie (1994), who searched for a larger-scale analog that fits the cold and dry summer as suggested by Mock (1991) and for an abnormally wet northern Great Plains. Both Mock (1991) and Blair and Rannie (1994) suggested that stronger westerlies and troughing over the western United States, with increased southwesterly flow at upper levels through the northern Plains, explain surface weather in the summer of 1849.

While most of the aforementioned studies focus on analogs of atmospheric pressure patterns to describe associated temperature and precipitation features of the past, Shinker et al. (2006) used atmospheric circulation variables (pressure and vertical motions) and energy- and water-balance variables from the NCEP-NCAR global reanalysis dataset (Kalnay et al., 1995; Kistler et al., 2001) to provide modern analogs for lake-level and moisture-balance trends from 11 000 to 8000 cal year BP. Their analysis focuses on the synoptic and dynamic controls of precipitation anomalies with an emphasis on the roles that large-scale vertical motions (omega) and surface feedbacks play in prolonged drought. One unique aspect of their modern synoptic analog approach was the interpretation of vertical motions at the 500 mb level via the variable omega, which is a secondary circulation feature embedded within ridges and troughs that provides information on sinking (within ridges) and rising (within troughs) motions that inevitably are the mechanisms that control the suppression or enhancement of precipitation, respectively. Their conceptual model explains the influence of atmospheric circulation on such precipitation mechanisms and regional moisture conditions in the present, in order to develop a more explicit understanding of the processes that can explain historic and prehistoric moisture anomalies. By illustrating the relationships between surface conditions, moisture availability, vertical motions, (omega) and surface water- and energy-balance components, they were able to demonstrate that dry conditions were not a result of anomalously strong zonal flow. Their results of modern analogs for mid-Holocene moisture patterns indicate that regional moisture flux and vertical motions can override the influence of broad circulation patterns.

This article presents two additional examples of modern synoptic analogs of past climates, using the NCEP-NCAR global reanalysis datasets, updating previous studies. Figure 3 illustrates August 1955, representing an analog for 6 ka as conducted by Mock and Brunelle-Daines (1999). The 500 mb geopotential height anomalies feature a strong upper-level anticyclone over the continent, likely creating widespread warmer-than-normal temperatures, and also being related to high specific humidity and increased monsoonal activity over the American Southwest (Figure 3). Two other centers of positive 500 mb height anomalies are indicative of a shifting long-wave pattern at the hemispheric scale. Heterogeneous patterns of omega at 500 mb are apparent, with strong sinking motions

Figure 3 Composite-anomaly maps for August 1955, a modern analog for 6 ka. Geopotential heights at the 500 mb level (a), omega (vertical velocity) at the 500 mb level (b), specific humidity at the 850 mb level (c), and precipitation rate at the surface (d). Composite anomalies are based on the 1981–2010 base period.

over the Great Basin likely related to widespread dryness which is reflected from proxy data (Mock and Brunelle-Daines, 1999; also see Harrison et al., 2003). January 1957 was demonstrated by Mock and Bartlein (1995) to be a close modern analog of western US paleoclimate for the Last Glacial Maximum, but this analog should not be over generalized for adjacent regions. Mean sea-level pressure anomalies and omega patterns of sinking motion are indicative of a strong high off the Northwest coast, enabling anomalous dry easterly flow into the Pacific Northwest (Figure 4). Conversely, negative pressure anomalies, rising motion, and high relative humidity are indicative of wetter conditions in the American Southwest as a result of increased troughing of the polar jet stream.

Circulation-to-Environment Approaches

The circulation-to-environment approach is generally opposite of that of the environment-to-circulation approach. It is based on hypotheses of the prevailing atmospheric circulation that occurred during the period and in the study area of interest. Modern climatic extremes that most resemble these hypotheses

are selected as the modern synoptic analogs, the atmospheric circulation of these extremes are next examined, and then the corresponding surface climatic anomalies are analyzed as well as compared with patterns as suggested by paleoclimatic proxy data. The relationships between patterns of surface anomalies in the modern analogs and those from paleoclimatic data test the reliability of the modern analogs. The circulation-to-environment approach eliminates the problem of having to distinguish multiple circulation patterns that may explain surface paleoclimate, but it needs to have a robust hypothesis on the prevailing atmospheric circulation that may have predominated during the past. Such hypothesis can be taken from the output of GCMs or other conceptual models.

Most studies utilizing the circulation-to-environment approach deal with the examination of paleoclimates at longer timescales. Willett (1950) was one of the first to conduct such an approach. He examined circulation patterns with low (meridional) Rossby wave indices to construct a map of late Pleistocene Northern Hemisphere general circulation, assuming that low indices represent periods conducive for glacial advance. This approach was updated by Dzerdzevskii (1969), using circulation indices covering a longer timeframe and suggested

January 1957

Mean sea-level pressure

Geopotential meters

Specific humidity 850 mb

g kg⁻¹

Omega (vertical velocity) 500 mb

Rising Pa s⁻¹ Sinking

Precipitation rate

kg m⁻² s⁻¹

Figure 4 Composite-anomaly maps for January 1957, a modern analog for 18 ka. Mean sea-level pressure (a), omega (vertical velocity) at the 500 mb level (b), specific humidity at the 850 mb level (c), and precipitation rate at the surface (d). Composite anomalies are based on the 1981–2010 base period.

associated surface climatic anomalies during glacial and interglacial periods. As for the hemispheric studies discussed earlier, these reconstructions are not representative of late Pleistocene paleoclimate because of the external and internal boundary conditions being dramatically different from what they are today.

Some scholars have incorporated a similar approach in using hemispheric indices, but they have also examined relationships between hemispheric circulation and regional-scale surface climate. Butzer (1957) examined high (zonal) and low (meridional) indices of hemispheric circulation from 1920 to 1950 for the Mediterranean, European, and North Atlantic regions. Next, he compared regional sea-level pressure patterns and associated temperature and precipitation patterns in the region with paleoclimatic proxy data from the Mediterranean region. He suggested that periods with high indices represent paleoclimate from glacial periods and that low (meridional) indices represent the paleoclimate from interglacial periods. This suggestion is opposite of that from Willett (1950), as Butzer implied that a specific meridional circulation type may apply to the glacial paleoclimate for the region. Barry (1960, 1966) examined synoptic patterns of vapor-flux-

convergence and snowfall from the winters of 1956–57 and 1957–58 that might relate and explain some processes responsible for glacial inception for Labrador-Ungava, Canada. He found no single circulation type solely responsible, but suggested generally that low hemispheric indices lead to increased snowfall and that high indices lead to low precipitation. Mean total transport of streamlines was found to be primarily from the west, but the mean eddy component was found to be from the south. Barry's (1960, 1966) and Butzer's (1957) studies on hemispheric/regional scale relationships may suggest that modern synoptic analogs may not be reliable at the continental or larger spatial scales.

Several studies based the selection of modern circulation extremes at smaller spatial scales, assuming that the analogies of past circulation at the smaller spatial scale still hold true during the modern record. Derbyshire (1971) classified seven primary circulation patterns that most commonly occur over Australia. Associated temperature and precipitation anomalies with these circulation types were next examined. Derbyshire (1971) then selected two winters of a 'disturbed' westerly synoptic type that most closely corresponded to the spatial distribution of cirques, implying that this synoptic pattern prevailed

more frequently during the Last Glacial Maximum. [Alt \(1983\)](#) identified several main 500 mb patterns that explain glacial mass balance for the Queen Elizabeth Islands. She extrapolated these modern synoptic relationships to explain circulation characteristics during the last 5000 years. She implied that the year-to-year variability of circulation is larger than the variability in the long-term trends, but that this observation is valid only for the Queen Elizabeth Islands. Results suggest that the atmospheric circulation for 5 ka was characterized by a dominant anticyclonic circulation, which is conducive for warmer conditions.

Circulation-to-environment approaches have not typically dealt with the examination of a hierarchy of climatic controls at different spatial scales. [Cockcroft et al. \(1987\)](#) used an analog model from [Tyson \(1986\)](#), which explains present-day synoptic relationships between circulation and dry and wet spells in South Africa, in order to explain paleoclimatic changes in the region in the last 21 000 years. The model from [Tyson \(1986\)](#) used regional-scale zonal and meridional indices, and extremes of these indices were found to relate to dry and wet spells. [Cockcroft et al. \(1987\)](#) selected several individual climatic extremes and noted that winter and summer rainfall regimes tend to respond inversely with one another as a result of topographic influences on larger-scale circulation changes. These patterns of spatial heterogeneity corresponded with patterns of paleoclimatic proxy data for most of the late Pleistocene. [Mock and Bartlein \(1995\)](#) used a somewhat different approach in their investigation of synoptic patterns that may have caused patterns of spatial heterogeneity for the western United States during 18 ka and 9 ka. They based their hypotheses of atmospheric circulation controls from the output of GCMs and selected the modern synoptic analogs from regional circulation indices. Next, they examined composite maps of temperature and precipitation responses at the surface for the climatic extremes and compared these patterns with effective moisture maps as suggested by paleoclimatic proxy data. [Mock and Bartlein's \(1995\)](#) results clearly indicate that modern synoptic analogs are extremely useful for showing the additional role of smaller-scale climatic controls, such as low-level topographic gaps, with larger-scale controls in order to explain patterns of spatial heterogeneity that are clearly evident from spatial patterns of paleoclimatic proxy data.

[Mock et al. \(1998\)](#) used a synoptic classification scheme to identify modern atmospheric circulation patterns in Beringia for January and July sea-level pressure, and July 500 mb height anomalies and their associated temperature and precipitation patterns. Although these synoptic patterns are not specifically paleoclimate analogs, they note that spatial heterogeneity of responses likely occurred in the past as a result of variations in the position of trough and ridge axes, in addition to the role of topography, indicating the value of synoptic typing for understanding spatially variable regional temperature and/or precipitation patterns.

Only a few studies have utilized the circulation-to-environment analog approach at shorter (historical) timescales. [Baerreis and Bryson \(1968\)](#) chose several modern climatic extremes over the United States on the basis of the strength of the westerlies and constructed a composite-difference map of precipitation. They implied that a pattern of strong westerlies corresponds to a climate that prevailed

around AD 1200, with the summer of 1974 being a prime example ([Bryson, 1981](#)). Such implications may hold true for some areas such as Iowa where stronger westerlies generally lead to drought, which was recorded by a variety of paleoclimatic evidence ([Bryson and Murray, 1977](#)), but accurately dated paleoclimatic proxy data are not spatially plentiful enough for arriving at a conclusion that such a pattern is valid for the entire United States. The composite-difference map by [Baerreis and Bryson \(1968\)](#) show some smaller-scale climatic variations, such as generally drier conditions in the Snake River Plain, and such variations are not yet recorded by proxy data. [Wishman \(1994\)](#) conducted a circulation-to-environment approach of the Little Ice Age and Medieval Warm Period temperature patterns for western Norway. He based his hypotheses of atmospheric circulation from [Lamb \(1987\)](#), stating that the Little Ice Age was caused by a southward displacement of the Icelandic low and that the Medieval Warm Period was characterized by a northward displacement of the Azores high. [Wishman \(1994\)](#) used August 1979 and August 1976 circulation as representative of the Little Ice Age and Medieval Warm Periods, respectively. The surface temperature responses showed much greater decreases in the Little Ice Age at higher elevations than the lowland valleys, perhaps related to the abandonment of summer farms.

Discussion and Conclusion

It is clearly evident from the review of literature discussed earlier that the primary goal of modern synoptic analogs of past climates was once to reconstruct synoptic patterns of atmospheric circulation. Research on synoptic analogs of the past was clearly more active prior to the advent of GCMs. As GCMs now provide a theoretical means of doing the reconstruction over longer timescales, this is no longer the primary goal of modern synoptic analogs, although some implications of possible circulation anomaly patterns from the analogs at and below the regional level are still valuable. However, the reconstruction of atmospheric circulation from modern climate analogs is still an important goal at the shorter (Little Ice Age) timescales, for areas of very diverse terrain, and they may be useful as analogs of past extreme events ([Barriopedro et al., 2011](#)). For both longer and shorter timescales, the primary goal of modern synoptic analogs has shifted toward a process/dynamic approach of climatic forcing mechanisms that may have predominated in the past. These component or process analogs provide additional information that complement both GCMs and RCMs to understand relationships between synoptic-scale circulation patterns with climatic responses at the surface. The examination of climatic responses is also not limited to conventional temperature and precipitation, but can also include geomorphic and biological processes.

The following issues that concern the application of synoptic modern analogs for paleoclimatic assessment are clearly evident throughout the literature review; these are issues of 1) spatial scale of the circulation and surface environments, 2) spatial coverage of modern as well as of paleoclimatic data, and 3) the research design of the analog approach. The first issue, spatial scale of circulation and the surface environment, deals with the size of the study area of interest for searching a

modern synoptic analog. In terms of longer (Quaternary) timescales, continental-to-hemispheric scale analogs do not exist because of dramatic changes in surface and external boundary conditions in the past. Large ice sheets, greater magnitudes of oceanic currents, and much greater summer insolation, for example, cannot be found in any present-day climatic extreme. As the spatial scale decreases, more synoptic analogs generally become available. Nevertheless, one must be cautious of depicting too small of a surface environment in an analog approach because of the difficulties encountered in clearly depicting an environment-to-circulation approach that corresponds to the paleoclimate of interest. For example, one cannot choose high annual precipitation years at a few sites in parts of the western United States as analogs because of the multiplicity of circulation regimes that cause the same anomalies (Kay, 1982). A larger spatial scale would enable one to more clearly define the surface climate environment that may correspond to that in the past.

Adequate spatial coverage of both modern instrumental and paleoclimatic proxy data is crucial for conducting a synoptic analog approach. As a result of the hierarchy of climatic controls at different spatial scales, modern instrumental and paleoclimatic proxy data must be spatially copious to depict areas of spatial heterogeneity. Problems concerning some paleoclimatic proxy data also arise because of possible lags and other uncertain responses to climatic change (Mock and Bartlein, 1995), although new multiproxy methods are becoming more readily available for syntheses (e.g., Neukom et al., 2010). Thus, without a proper interpretation of paleoclimatic data, misleading patterns of spatial heterogeneity may result. Modern synoptic analogs conducted in a circulation-to-environment approach do not provide a means to reconstruct spatial patterns of paleoclimate; they only provide an understanding of processes that may have occurred in the past, and this requires a spatially detailed network of paleoclimatic proxy data. Researchers must also use the proper size grids of circulation data that represent all the synoptic features of interest (e.g., Pacific subtropical high; Siberian high) in their studies.

Neither the environment-to-circulation nor the circulation-to-environment approach shows any clear advantage; the choice depends on the timescale, region, and availability of data. The environment-to-circulation approach is largely inductive, being based heavily on how the surface environment is defined, and misinterpretations of surface data and poor theory can lead to erroneous implications of atmospheric circulation. The circulation-to-environment approach does not have the problem of defining a surface environment, but it is based on hypotheses of the prevailing circulation of the past, thus a clear framework of the climatic controls and the hypotheses must be formulated. The literature review has stated that generally the environment-to-circulation approach is more common in conducting synoptic analog studies. This is particularly true in terms of earlier studies dealing with longer timescales, because the primary goal was to reconstruct past atmospheric circulation. Studies dealing with shorter timescales still commonly employ such an approach because scholars are searching for circulation patterns that explain spatial variations of surface climatic proxy data responses. Longer timescale studies can use GCM output to conduct a circulation-to-environment approach; few similar studies

have been applied for shorter timescales. Yet, opportunities exist to conduct circulation-to-environment approaches for shorter timescales as better and more GCM simulations become available, as networks of proxy data improve spatially, and as a better understanding of hypotheses of climatic controls and synoptic patterns in the past for individual regions is achieved (Saenger et al., 2009; Palastanga et al., 2010; Luterbacher et al., 2010). Additionally, recent development of data sources (via reanalysis products) that have global and/or regional coverage representing surface and atmospheric variables are able to capture synoptic and dynamic processes and thus provide new opportunities for modern analog interpretations that focus on specific climatic mechanisms for understanding paleoenvironmental conditions (Shinker et al., 2006). Overall, both analog approaches, when exercised properly, make valuable contributions in interpreting past climates and will continue to do so as long as they have advantages over other methods in analyzing the hierarchy of climatic controls.

Early Cenozoic Warm Times

At the start of the Cenozoic, the planet was ice-free; there was no sea ice in the Arctic Ocean and there was no Greenland or Antarctic ice sheet. Benthic Foraminifera $\delta^{18}\text{O}$ document a long-term cooling of the global deep ocean during the Cenozoic (Zachos et al., 2001). Because oceanic bottom waters originate in the polar oceans, Arctic climate history is broadly consistent with the global deep-ocean record. Although general cooling and an increase in terrestrial ice volume characterize the Cenozoic, this first-order was punctuated by short- and longer-lived climate reversals, by variations in cooling rate, and by additional features related to growth and shrinkage of ice once ice sheets were well established. A detailed Arctic Ocean record that is equivalent to the global record is not yet available. Because the Arctic Ocean is connected to the global ocean only by a single narrow deep channel and some intermittently exposed shallow shelves, the Arctic Ocean $\delta^{18}\text{O}$ record often differs from that of the global ocean, hindering correlations. Emerging paleoclimate reconstructions from the Arctic Ocean derived from sediments recovered from the Lomonosov Ridge (Polyak et al., 2010) shed new light on the Cenozoic evolution of the Arctic Basin, but the data have yet to be fully integrated with evidence from high-latitude terrestrial records or with the other records from elsewhere in the Arctic Ocean. The presence of trace amounts of coarse clastic debris may indicate early onset of Arctic Ocean sea ice or calving land ice, but the evidence remains circumstantial and alternative explanations are possible.

General cooling through the Cenozoic is attributed mainly to a slow drawdown of greenhouse gases in the atmosphere through the weathering of silicic rocks that exceeded the release of stored carbon through volcanism and reprocessing. Many lines of proxy evidence show that atmospheric CO_2 was higher in the Cretaceous than it has been recently, and that it subsequently fell in parallel with the cooling. Changes in continental positions, sea level, and oceanic circulation as well as biological evolution also may have contributed, but are lesser factors.

Pliocene Warmth and the Transition into Quaternary Ice-Age Cycles

During the middle Pliocene (~3.5 Ma), forests occupied large regions near the Arctic Ocean that are currently polar deserts. Fossils of the marine bivalve *Arctica islandica*, which does not live where there is seasonal sea ice, found in marine deposits as young as 3.2 Ma old on Meighen Island at 80°N, likely record the peak Pliocene warmth of the ocean (Fyles et al., 1991). Multiple temperature proxies from terrestrial peat in the high Canadian Arctic indicate mean annual Pliocene temperatures 19 °C higher than present (Ballantyne et al., 2010); other sites have produced large temperature differences for the Pliocene of the North American Arctic, although slightly lower magnitudes (14 °C, Ellesmere Is., Ballantyne et al., 2006; beetles and plants indicative of summers as much as 10 °C warmer than recently measured temperatures and even larger wintertime warming to

a maximum of 15 °C or more, [Elias and Matthews, 2002](#)). Although continental configurations were similar to modern forests extended to the Arctic shoreline, nearly eliminating the Arctic tundra biome, and sea level stood ~25 m higher than present, implying much smaller Greenland (possibly limited to small mountain ice caps and glaciers) and Antarctic ice sheets (possibly without a West Antarctic Ice Sheet).

Explaining the warmth of the Arctic during the Pliocene remains enigmatic. The duration of warmth exceeds cycle-lengths related to orbital irregularities ($>10^5$ years), and continental configurations and gateways were similar to the present day. It is likely that the ocean transported more heat into the Arctic from the Atlantic during peak Pliocene warmth ([Haywood et al., 2009](#)), although the status of Arctic Ocean sea ice remains uncertain, as does the amount of ice on Greenland. Best estimates of atmospheric CO₂ loadings are similar to present (AD 2011) levels ([Pagani et al., 2010](#)), although most climate models driven by changes in greenhouse gases (mostly CO₂) tend to underestimate Arctic warmth (e.g., [Sloan and Barron, 1992](#)). A consensus view is that greater atmospheric and/or oceanic meridional heat transport, coupled with some combination of stronger greenhouse gas forcing and stronger long-term positive feedbacks than those found in many climate models, are required to explain the reconstructed temperatures for the Arctic during the warmest intervals of the Pliocene.

The Early Quaternary

The development of large continental ice sheets in the North American and Eurasian Arctic marks the onset of the Quaternary. The first secure evidence for the growth of these ice sheets is the appearance of ice-rafted debris (IRD) in the central North Atlantic between 3.0 and 2.5 Ma, far from shores where seasonal sea ice may transport sediment. Recently, the International Union of Geological Sciences has formalized a revision of the geological timescale that places the base of the Quaternary Period at 2.58 Ma, coincident with the Gauss–Matuyama paleomagnetic reversal ([Gibbard et al., 2010](#)), and closely aligned to the start of the ice-age cycles. The full Quaternary is best represented in deep-sea sediment, where the changes in $\delta^{18}\text{O}$ of benthic Foraminifera are used to subdivide the Quaternary into 104 numbered marine isotopic stages (MIS), counting consecutively back from the present ([Lisiecki and Raymo, 2005](#)), with odd-numbered stages representing global warm times/minimum ice volumes, and even-numbered stages representing peak ice volumes.

The appearance of large, quasistable continental ice sheets coincides approximately with the start of the Quaternary, but general cooling through the Cenozoic is reflected by the appearance of smaller glaciers and ice caps much earlier, during the Pliocene and possibly earlier. Although the pattern of glacial onset over Greenland remains uncertain, small amounts of IRD are found in marine sediment recovered from the continental shelf around Greenland as old as 7 Ma ([St. John and Krissek, 2002](#)). IRD in proximal marine sediment, but not in the central Atlantic, likely indicates that climate cooled sufficiently during the Pliocene and possibly even as early as the late Miocene, to allow small ice caps and glaciers to form at high elevations on Greenland. Outlet glaciers delivering small

icebergs to the sea during the coldest intervals likely explains the observed IRD, but the total ice volume on Greenland may have been very small. Indeed, the first significant appearance of likely Greenland-derived IRD in the open ocean is observed at ~3.2 Ma ([Kleiven et al., 2002](#)), which may represent the inception of a Greenland Ice Sheet, although the geographic distribution suggests Scandinavia and North America are also potential sources. Widespread IRD in the North Atlantic begins about 2.7 Ma ([Kleiven et al., 2002](#)), at about the onset of the Quaternary.

The best terrestrial record of the early phases of late Cenozoic ice growth comes from Iceland, where unusually high volcanic productivity, caused by the superposition of mantle plume and mid-ocean ridge magmatism, resulted in an environment where constructive geologic processes exceed destructive processes. This unusual state results in the unique preservation of glacial deposits in Iceland extending well back into the Pliocene. Because lava flows can only occur if the landscape is ice-free, the general consensus is that such flows represent interglacials, interstadials, or other ice-free periods, whereas hyaloclastites (subglacially formed volcanics) and till represent glaciations. Consequently, a record of past glaciations (often including ice-flow features) and interglaciations is preserved within stacked volcanic sequences. Mapping and dating of remnants of glacial deposits found imbedded within the lava flows of Iceland have revealed at least 22 glacial–interglacial cycles during the last ~3 Ma ([Geirsdóttir et al., 2011](#)). Four phases of glaciation have been identified: (1) The inception phase, between >4 and 3 Ma, when ice caps were concentrated over the mountainous regions in the south-east of Iceland. (2) A transitional growth phase (3.0–2.5 Ma), when the ice sheet(s) extended their margins to the north and west, reaching the sea in the north by Tjörnes by 2.5 Ma. (3) The presence of glacial deposits across all of the highlands by 2.5–2.4 Ma, suggests that progressive cooling resulted in continued incremental north and westward growth of the Quaternary ice sheet from its nucleus in southeast Iceland. By this time, the ice sheet covered more than half of the island. (4) Shortly afterwards, between 2.5 and 2.2 Ma, a single ice sheet covered the whole of Iceland for the first time, reaching the modern shoreline, and full-scale glacial–interglacial cyclicity was established ([Geirsdóttir, 2011](#)).

For the first 1.5–2.0 Ma of the Quaternary, cycles of waxing and waning continental glaciation appeared at 41 ka intervals, as the climate oscillated between glacial and interglacial states. Among the prominent but interglaciations during this period is one at about 2.4 Ma that is especially well represented by the Kap København Formation, a 100-m-thick sequence of estuarine sediments that covered an extensive lowland area near the northern tip of Greenland ([Funder et al., 2001](#)). The rich and well-preserved fossil fauna and flora in the Kap København Formation record warming from cold conditions as interglaciation, followed by cooling during the subsequent 10–20 ka. During the peak warmth, forest trees reached the Arctic Ocean coast, 1000 km north of the northernmost trees today. Based on this warmth, [Funder et al. \(2001\)](#) suggested that the Greenland Ice Sheet must have been reduced to local ice caps in mountain areas. Although finely resolved time records are not available throughout the Arctic Ocean of that time, by analogy with present faunas along the Russian coast,

the coastal zone would have been ice-free for 2–3 months in summer. Today, this coast of Greenland experiences year-round sea ice, and models of diminishing sea ice in a warming world generally indicate long-term persistence of summertime sea ice off these shores (e.g., [Holland et al., 2006](#)). Thus, the reduced sea ice off northern Greenland during deposition of the Kap København Formation suggests a widespread interglaciation during which Arctic sea ice was greatly diminished, and possibly absent in summer.

During the warm interval described above, precipitation was greater and temperatures were higher than at the peak of the current interglaciation, about 8 ka, and the temperature difference was larger during winter than during summer. Higher temperatures were not caused by notably greater solar insolation, owing to the relative repeatability of the Milankovitch variations over millions of years (e.g., [Berger et al., 1992](#)). Uncertainties in atmospheric CO₂ concentration, ocean heat transport, and perhaps other factors at the time of the Kap København Formation are sufficiently large to preclude strong conclusions about the causes of the unusual warmth.

Potentially correlative records of warm Early Quaternary interglacial conditions are found in deposits along coastal plains in northern and western Alaska. Interglacial marine transgressions that repeatedly flooded the Bering Strait modified the configuration of adjacent coastlines, altered regional continentality, and reinvigorated the exchange of water masses between the North Pacific, Arctic, and North Atlantic oceans. Since the first submergence of the Bering Strait about 5.5–5.0 Ma ([Marincovich and Gladenkov, 2001](#)), this marine gateway allowed relatively warm Pacific water to reach as far north as the Beaufort Sea ([Brigham-Grette and Carter, 1992](#)). The Gubik Formation of northern Alaska records at least three warm high sea stands in the early Quaternary. During the Colvillian transgression, about 2.7 Ma, the Alaskan Coastal Plain supported open boreal forest or spruce–birch woodland with scattered pine and rare fir and hemlock ([Nelson and Carter, 1991](#)). Warm marine conditions are confirmed by the general character of the ostracode fauna, which includes *Pterygocythereis vannieuwenhuisei* ([Brouwers, 1987](#)), an extinct species of a genus whose modern northern limit is the Norwegian Sea and which, in the northwestern Atlantic Ocean, is not found north of the southern cold-temperate zone ([Brouwers, 1987](#)). Despite the high sea level and relative warmth indicated by the Colvillian transgression, erratic boulder in Colvillian deposits southwest of Barrow, Alaska, indicate that glaciers then terminated in the Arctic Ocean and produced icebergs large enough to reach northwest Alaska.

The subsequent Bigbendian transgression (about 2.5 Ma), characterized by rich molluscan faunas including the gastropod *Littorina squalida* and the bivalve *Clinocardium californiense* ([Carter et al., 1986](#)), indicates renewed warmth along northern Alaska. The modern northern limit of both of these mollusk species is well to the south (Norton Sound, Alaska). The presence of sea otter bones suggests that the limit of seasonal ice on the Beaufort Sea was restricted during the Bigbendian interval to positions north of the Colville river and thus well north of typical twentieth century positions ([Carter et al., 1986](#)); modern sea otters cannot tolerate severe seasonal sea-ice conditions ([Schneider and Faro, 1975](#)).

The Fishcreekian transgression (about 2.4–2.1 Ma) has been correlated with the Kap København Formation on Greenland ([Brigham-Grette and Carter, 1992](#)). However, age control is imprecise, and [Brigham \(1985\)](#) and [Goodfriend et al. \(1996\)](#) suggested that the Fishcreekian could be as young as 1.4 Ma. This deposit contains several mollusk species that currently are found only south of the winter sea ice margin. Moreover, sea otter remains and the intertidal gastropod *L. squalida* at Fish Creek suggest that perennial sea ice was absent or severely restricted during the Fishcreekian transgression ([Carter et al., 1986](#)). Correlative deposits rich in mollusk species that currently live only well to the south are reported from the coastal plain at Nome, Alaska ([Kaufman and Brigham-Grette, 1993](#)).

The available data clearly indicate episodes of relatively warm conditions that correlate with high sea levels and reduced sea ice in the early Quaternary. The high sea levels suggest the melting of land ice. Thus, the correlation of warmth with diminished ice on land and at sea is analogous to features of contemporary change, as indicated by recent instrumental observations, model results, and data from other time intervals.

The Mid-Pleistocene Transition: 41 and 100 ka Worlds

Throughout the Quaternary the cyclical waxing and waning of continental ice sheets has dominated global climate variability in response to variations in solar insolation caused by features of Earth's orbit. After the onset of glaciation in North America, ice growth and decay occurred on the same frequency as the Earth's obliquity (tilt), a 41 ka cycle. But between 1.2 and 0.7 Ma, the variations in ice volume became larger and the periods much longer, averaging approximately 100 ka between interglaciations by 700 ka. Although Earth's eccentricity varies with an approximately 100 ka period, this variation results in only small changes in solar insolation in the key regions of ice growth, far less than precession and obliquity cycles, so eccentricity is unlikely to be the cause of this change; the reason for the dominant 100 ka period in ice volume remains debated.

The MPT is of particular interest because it was not caused by any major change in Earth's orbital behavior, and so the transition likely reflects a fundamental threshold within the climate system. Models for the 100 ka variability commonly assign a major role to the ice sheets themselves and especially to the Laurentide Ice Sheet, which dominated the total global change in ice volume. [Roe and Allen \(1999\)](#) assessed six different explanations of this behavior and found that all fit the data rather well; no one model has superiority over another.

A key observation that must be satisfied in any explanation for the mid-Pleistocene transition (MPT) is that the ice sheets of the last 700 ka were larger in volume but smaller in area than were the largest early Quaternary ice sheets ([Balco et al., 2005a,b](#)). [Clark and Pollard \(1998\)](#) used this observation to argue that the early Laurentide Ice Sheets must have had a substantially lower surface elevation than in the late Pleistocene, possibly by as much as 1 km. They argued that at the onset of the Quaternary, ice sheets advanced over easily deformed water-saturated weathered terrain. The low basal shear strength allowed fast ice flow, producing aerial extensive, but relatively thin ice sheets. Successive glacial cycles gradually

eroded the regolith, eventually exposing irregular bedrock in the central region. With increased resistance to basal sliding, the ice sheets eventually became thicker with a steeper surface profile, but not quite as extensive aerially as the early Quaternary ice sheets, despite their greater ice volume.

Other hypotheses emphasize the gradual global cooling that began in the early Cenozoic and continued through much of the Quaternary (Raymo et al., 2006; Ruddiman, 2003). For example, cooling may have passed a threshold whereby ice sheets attained sufficient thickness in their growth phase that the duration of the 'warm' portion of the 41 ka tilt cycle was too short to melt enough ice to cause deglaciation. Then the 100-ka cycle may result from the cumulative build up of the Laurentide Ice Sheet until it was sufficiently thick that it finally trapped enough of Earth's internal heat to thaw the ice-sheet bed, and the consequent faster ice flow lead to deglaciation. Marshall and Clark (2002) modeled the growth and decay of the Laurentide Ice Sheet and found that during growth the ice was frozen to its bed, decreasing flow velocities. After many tens of thousands of years, the modeled ice had thickened sufficiently to trap enough geothermal heat to thaw the bed, which allowed faster flow. Faster flow of the ice sheet lowered the surface gradient, which allowed warming and melting. Behavior such as that described could cause the main variations of ice volume to be slower than the orbitally driven variations in insolation. Alternative hypotheses require interactions in the Southern Ocean between the ocean and sea ice and between the ocean and the atmosphere (Gildor et al., 2002). For example, Toggweiler (2008) suggested that because of the close connection between the southern westerly winds and meridional overturning circulation in the Southern Ocean, shifts in wind fields could control the exchange of CO₂ between the ocean and the atmosphere. Carbon models support the notion that weathering and the burial of carbonate can be perturbed in ways that alter deep ocean carbon storage and result in 100 ka CO₂ cycles. Others have suggested that 100 ka cycles and CO₂ might be controlled by variability in obliquity cycles (i.e., two or three 41 ka cycles that produce a mixture of 80 and 120 ka cycles after 700 ka; Huybers, 2006, 2007, or by variable precession cycles altering the 19 and 23 ka cycles; Raymo, 1997). Ruddiman (2006) furthered these ideas but suggested that since 900 ka, CO₂-amplified ice growth continued at the 41 ka intervals but that polar cooling dampened ice ablation. His CO₂-feedback hypothesis suggests a mechanism that combines the control of 100 ka cycles with precession cycles (19 and 23 ka) and with tilt cycles (41 ka).

Other hypotheses also exist for these changes. A complete explanation of the onset of extensive glaciation on North America and Eurasia at the beginning of the Quaternary, and of the MPT from 41 to 100 ka ice-age cycles, remain the object of ongoing investigations.

A Link Between Ice Volume, Air Temperature, and Greenhouse Gases

The globally averaged temperature decrease during the 100-ka ice-age cycles since the MPT was about 5–6 °C (Jansen et al., 2007). Larger decreases are calculated for the Arctic and close

to the ice sheets, with a decrease of ~22 °C atop the Greenland Ice Sheet at the Last Glacial Maximum (LGM; Cuffey et al., 1995). The total change in solar radiation reaching the planet during these cycles was near zero; orbital features served primarily to change insolation seasonally and geographically.

Many factors probably contributed to this large temperature change despite the small global change in total insolation. Cooling produced growth of reflective ice that increased the planetary albedo, while the great height of the ice sheets on its own reduced Arctic temperatures as well. But changes in atmospheric greenhouse gases are necessary to explain the magnitude of the global cooling.

Antarctic ice cores now provide us with accurate estimates of atmospheric trace gas concentrations for the past 800 ka (Lüthi et al., 2008, and references therein). Complex changes, especially in the ocean, reduced atmospheric carbon dioxide concentrations during glaciations, and both oceanic and terrestrial changes reduced atmospheric water vapor, methane, and nitrous oxide, all of which are greenhouse gases. The changes in water vapor and carbon dioxide were most important in the planetary energy balance. Increasing aridity in some areas and glacial outwash in others produced additional dust that reduced the flux of insolation reaching the planet's surface (e.g., Mahowald et al., 2006). Cooling caused regions formerly forested to give way to grasslands, tundra or dune fields, further increasing the planetary albedo. While Earth's orbital features paced the ice-age cycles, strong positive feedbacks are required to provide quantitatively accurate explanations of the observed glacial and interglacial changes.

The relation between climate and carbon dioxide has been strongly correlated for at least the past 800 ka (Lüthi et al., 2008), and the growth and shrinkage of ice, cooling and warming of the globe, and other changes have repeated along similar, although not identical paths.

Marine Isotopic Stage 11 – A Long Interglaciation

Following the MPT, the growth and decay of ice sheets followed a 100 ka cycle: brief, warm interglaciations lasted 10 to about 40 ka, after which ice progressively increased in volume to a maximum, before ice volumes decreased rapidly and the planet transitioned into the next interglaciation. Although this 100 ka cycle is unlikely to be linked to changes in the 100 ka eccentricity cycle because it produces so little a change in solar energy reaching the Earth, there is an additional ~400 ka orbital cycle; Earth's orbit goes from almost round to more eccentric to almost round in about 100 ka, but the maximum eccentricity reached in these 100-ka cycles increases and decreases within a 400-ka cycle (Berger and Loutre, 1991). When the orbit is almost round, there is little effect from Earth's precession. But, about 400 ka, during MIS 11, the 400-ka cycle caused a nearly round orbit to persist, and the interglaciation as recorded in both ice cores and marine sediment lasted longer than previous or subsequent warm times (Jouzel et al., 2007). When Earth's orbit is nearly round, there is little change in insolation during a precession cycle. Consequently, summer insolation at high northern latitudes may not have become low enough at the end of the first 11 ka precession hemisphere to allow ice growth in the Arctic.

Mid- and low-latitude paleoclimate records show that MIS 11 lasted ~30 ka, rather than the typical 10 ka duration, but sediments containing MIS 11 are rare in the Arctic and their temperature signals are inconclusive (see [Helmke and Bauch, 2003](#), and references therein). Sea level during MIS 11 was higher than at any time since (cf. [Olson and Hearty, 2009](#)), and data from Greenland are consistent with notable shrinkage or loss of the ice sheet accompanying the long warmth, although the dating is poorly constrained ([Willerslev et al., 2007](#)).

Marine Isotopic Stage 5e: The Last Interglaciation

The warmest millennia of at least the past 250 000 years occurred during MIS 5, and especially during the warmest part of that interglaciation, MIS 5e ([Bauch et al., 1999](#); [Fronval and Jansen, 1997](#); [Kukla, 2000](#); [McManus et al., 1994](#)). During MIS 5e Earth's orbital parameters aligned to produce a strong positive anomaly in solar radiation during summer throughout the Northern Hemisphere ([Berger and Loutre, 1991](#)). Between 130 and 127 ka, the average solar radiation during the key summer months (May, June, and July) was about 11% greater than solar radiation at present throughout the Northern Hemisphere, and a slightly greater anomaly, 13%, existed over the Arctic. Greater solar energy in summer lead to melting of the Laurentide and Fennoscandinavian ice sheets earlier, during the precession cycle than during the last deglaciation. Sea level was higher than present 129 ka, coincident with the Northern Hemisphere insolation peak, whereas sea level only reached present in the Holocene about 6 ka, 5 ka after the peak in Northern Hemisphere insolation ([CAPE Last Interglacial Project Members, 2006](#)). The large insolation anomaly and intensification of the North Atlantic Drift combined to reduce Arctic Ocean sea ice, allow expansion of boreal forest to the Arctic Ocean shore throughout large regions, reduce permafrost, and melt almost all glaciers in the Northern Hemisphere ([CAPE Last Interglacial Project Members, 2006](#)).

High solar radiation in summer during MIS 5e, amplified by key boundary-condition feedbacks (especially sea ice, seasonal snow cover, and atmospheric water vapor), collectively produced summer temperature anomalies 4–5 °C above present over most Arctic lands ([CAPE Last Interglacial Project Members, 2006](#)), substantially above the average Northern Hemisphere summer temperature anomaly (1 ± 1 °C above present). MIS 5e demonstrates the strength of positive feedbacks on Arctic warming ([Miller et al., 2010b](#)).

Terrestrial MIS 5e Records

Summers throughout the Arctic were warmer during MIS 5e than at present, but the magnitude of warming differed spatially. Positive summer temperature anomalies were largest around the Atlantic sector, where summer warming was typically 4–6 °C higher than present. This anomaly extended into Siberia, but it decreased from Siberia westward to the European sector (0–2 °C), and eastward toward Beringia (2–4 °C). The Arctic coast of Alaska had sea-surface temperatures 3 °C above recent values and considerably less summer sea ice than recently, but much of interior Alaska had smaller anomalies

(0–2 °C) that probably extended into western Canada. In contrast, northeastern Canada and parts of Greenland had summer temperature anomalies of about 5 °C, and perhaps more. A stratified lacustrine sequence from the eastern Canadian Arctic that captures MIS 7, MIS 5e, and the Holocene, suggests that for at least this portion of the Arctic, only full interglacials were warm enough for lakes to be ice-free in summers long enough for the preservation of biotic-bearing sediment; the record also suggested that twentieth century warming represents a no-analog situation for the lake ([Axford et al., 2009](#)).

Precipitation and winter temperatures are more difficult to reconstruct for MIS 5e than are summer temperatures. In northeastern Europe, the latter part of MIS 5e was characterized by a marked increase in winter temperatures. A large positive winter temperature anomaly also occurred in Russia and western Siberia, although the timing is not as well constrained ([Funder et al., 2002](#); [Gudina et al., 1983](#); [Troitsky, 1964](#)). Qualitative precipitation estimates for most other sectors indicate wetter conditions than in the Holocene.

Marine MIS 5e Records

Low sedimentation rates in the central Arctic Ocean and the rare preservation of carbonate fossils limit the number of sites at which MIS 5e can be reliably identified in sediment cores. Peak concentrations of a foraminifer species that usually dwells in subpolar waters were found in MIS 5e zones and interpreted to indicate relatively warm interglacial conditions and much reduced sea-ice cover in the interior Arctic Ocean ([Adler et al., 2009](#); [Nørgaard-Pedersen et al., 2007a,b](#)). Interpretation of these and other proxies is complicated by the strong vertical stratification in the Arctic Ocean; today, warm Atlantic water (>1 °C) is in most areas isolated from the atmosphere by a relatively thin layer of cold (<–1 °C) low-salinity surface water, limiting the transfer of heat to the atmosphere. It is not always possible to determine whether subpolar Foraminifera found in Arctic Ocean sediment cores lived in warm waters that remained isolated from the atmosphere below the cold surface layer, or whether the warm Atlantic water had displaced the cold surface layer and was interacting with the atmosphere and affecting its energy balance.

Landforms and fossils from the western Arctic and Bering Strait indicate substantially reduced sea ice during MIS 5. The winter sea-ice limit is estimated to have been as much as 800 km farther north than its average twentieth century position, and summer sea ice was likely to have been much reduced relative to present ([Brigham-Grette and Hopkins, 1995](#)). These reconstructions are consistent with the northward migration of treeline by hundreds of kilometers throughout much of Alaska and the expansion of treeline to the Arctic Ocean coast in the Far East of Russia ([Lozhkin and Anderson, 1995](#)).

Marine Isotopic Stage 3 (70–30 ka): Rapid Climate Oscillations

The Arctic climate history through MIS 3 is difficult to reconstruct because of the paucity of continuous records and the

difficulty in providing a secure time frame. Continental ice sheets were reduced, relative to ice volumes during MIS 2 and MIS 4, and sea level was slightly higher, but the coastline was still well offshore in most places. The $\delta^{18}\text{O}$ record of temperature over the Greenland Ice Sheet and other ice-core data show that the North Atlantic region experienced repeated abrupt climate oscillations between fully glacial and interstadial conditions throughout MIS 3. These oscillations, known as Dansgaard-Oeschger (DO) events, each lasted several hundred to a few thousand years, with temperatures changing by as much as 15°C (Alley, 2007, and references therein). Similar climate excursions are also recorded in cave sediments from China and Yemen (Burns et al., 2003; Dykoski, et al., 2005; Wang et al., 2001), in high-resolution marine records off California (Behl and Kennett, 1996), and sediment cores from the Cariaco Basin (Hughen et al., 1996), the Arabian Sea (Schulz et al., 1998) and the Sea of Okhotsk (Nürnberg and Tiedemann, 2004), among many other sites. Rapid climate changes within MIS 3 were thus hemispheric to global in nature and are considered a sign of large-scale coupling between the cryosphere, ocean, and atmosphere. Although the cause of these events is still debated, they were likely the result of abrupt reorganizations of the ocean's thermohaline circulation, probably related to inherent ice sheet instabilities that introduced large quantities of icebergs and fresh water into the North Atlantic (MacAyeal, 1993).

The terrestrial Arctic vegetation record reflects increased continentality that very likely contributed to relatively high summer temperatures that presumably were offset by colder winters. Variable paleoenvironmental conditions were typical of the MIS 3 (Karaginskii) period throughout Arctic Russia, although regional correlations are difficult. However, evidence for repeated abrupt temperature oscillations is weak, possibly because of the difficulty of obtaining precise dates in this time range. On the New Siberian Islands, Andreev et al. (2001) document the existence of graminoid-rich tundra covering wide areas of the emergent shelf during MIS 3, with summer temperatures possibly 2°C higher than during the twentieth century. At Elikchan 4 Lake in the upper Kolyma drainage, the sediment record contains at least three MIS 3 intervals when summer temperatures and treeline reached late Holocene conditions (Anderson and Lozhkin, 2001). MIS 3 insect faunas in the lower Kolyma are thought to have thrived in summers that were $1\text{--}4.5^\circ\text{C}$ higher than recently (Alfimov et al., 2003).

The warmest widespread MIS 3 interval in Beringia occurred 44–35 ka (Anderson and Lozhkin, 2001); it is well represented in proxies from interior sites, although there is little or no vegetation response in areas closest to Bering Strait. Summer warmth appears to have been strongest in eastern Beringia where temperatures were only $1\text{--}2^\circ\text{C}$ lower than at present between 45 and 33 ka (Elias, 2007). The warmest interval in interior Alaska (Fox Thermal Event), about 40–35 ka, was marked by spruce forest tundra, although in the Yukon, forests were most dense a little earlier, about 43–39 ka (Anderson and Lozhkin, 2001).

The transition from MIS 3 to MIS 2 is marked by a shift from warm-moist to cold-dry conditions in western Beringia, but is absent or subtle in all but a few records in Alaska (Anderson and Lozhkin, 2001).

Marine Isotopic Stage 2 (30–15 ka): The LGM

The LGM was cold globally, but particularly cold in the Arctic. Planetary temperatures were $5\text{--}6^\circ\text{C}$ lower than at present (Jansen et al., 2007), whereas mean annual temperatures in central Greenland were depressed more than 20°C (Cuffey et al., 1995), with a similar summer temperature reduction estimated for Beringia (Elias et al., 1996). Much of the Arctic lands lay beneath continental ice sheets, and the Arctic Ocean was mantled by a continuous cover of sea ice and entrapped icebergs (Bradley and England, 2008). The lack of ocean-atmosphere transfer of heat during winter months would result in exceptionally cold winters, not only over the Arctic Ocean proper, but also across adjacent lands. These factors together limit the direct records of LGM climate across most of the Arctic. The available evidence for terrestrial ecosystems suggests that low- and high-shrub tundra were extremely restricted during the LGM, and largely replaced by polar desert or graminoid and forb tundra and an intergradation of steppe and tundra in the north Eurasian interior (Bigelow et al., 2003), ecosystem changes consistent with cold, dry climates with little snow cover.

Global ice volumes peaked about 21 ka. Rising solar insolation across the Northern Hemisphere in summer and increases in greenhouse gases caused Northern Hemisphere ice sheets to begin to recede from their maxima shortly after 20 ka, with the rate of recession increasing noticeably after about 16 ka (see, e.g., Clark et al., 2004; Dyke et al., 2003). Most coastlines became ice-free before 12 ka, and ice continued to melt rapidly as Northern Hemisphere summer insolation reached a peak ($\sim 9\%$ above modern) about 11 ka.

A major climate reversal during the deglacial cycle, the Younger Dryas, was initially recognized in pollen records from northwest Europe, and is now formally defined by the large isotopic excursion in the Greenland Ice Sheet cores, between 12.9 and 11.7 ka (Rasmussen et al., 2006). It can be considered that last of the large DO events, with its strongest expression centered on the northern North Atlantic, and downstream into Eurasia, but also effecting to a lesser degree the rest of the Northern Hemisphere.

Marine Isotopic Stage 1, The Holocene

The transition from MIS 2 to MIS 1, which marks the start of the Holocene, is commonly placed at the abrupt termination of the Younger Dryas cold event, about 11.7 ka (Rasmussen et al., 2006). By 8 ka the main unstable Northern Hemisphere ice sheets had been reduced in size that there impacts on Arctic climate was minimal, and by 6 ka, sea level and ice volumes were close to present, and greenhouse gases in the atmosphere differed little from preindustrial conditions (e.g., Jansen et al., 2007). The Holocene is identified as a separate epoch, not because the climate of the present interglaciation is particularly noteworthy, but because it is the period when humans became significant agents of geological change.

Holocene Thermal Maximum

A wide variety of evidence from terrestrial and marine archives indicates that peak Holocene Arctic summertime warmth was

achieved during the early Holocene, when most regions of the Arctic experienced sustained summer temperatures that exceeded the observed twentieth century values. This period of peak warmth, is geographically variable in its timing (Kaufman et al., 2004). The ultimate driver of the warming was orbital forcing, which produced increased summer solar radiation across the Northern Hemisphere. At 70° N June insolation 11 ka was about 45 W m⁻² larger than present, for a total change of about 9% (Berger and Loutre, 1991). January insolation did not change because there is no insolation that far north in January. Consequently, the net annual insolation change for the Arctic during a precession cycle exceeds that of lower latitudes.

High-resolution (decades to centuries) archives containing multiple climate proxies are available for most of the Holocene throughout the Arctic. Consequently, the Holocene record allows evaluation of the range of natural climate variability and of the magnitude of climate change in response to relatively small changes in forcings. Most Arctic paleoenvironmental records for the Holocene thermal maximum (HTM) record primarily summer temperatures. Many different proxies have been exploited to derive these reconstructions, including biological proxies (pollen, diatoms, chironomids, dinoflagellate cysts, and other microfossils), elemental and isotopic geochemical indices from lacustrine and marine sediments and ice cores, borehole temperatures, age distributions of radiocarbon-dated tree stumps north of (or above) current treeline, and the extralimital distributions of thermophilous marine invertebrates and whales.

A synthesis of 140 Arctic paleoclimatic and paleoenvironmental records extending from Beringia westward to Iceland (Kaufman et al., 2004) outlines the nature of the HTM in the western Arctic. The HTM has an average duration of 2.1 ka in Beringia to 3.5 ka in Greenland. The interval from 10 to 4 ka contains the greatest number of sites recording HTM conditions and the greatest spatial extent of those conditions in the western Arctic. The HTM began earliest in Beringia, where warmer-than-present summers became established 14–13 ka. Intermediate ages for HTM initiation (10–8 ka) are apparent in the Canadian Arctic Archipelago and in central Greenland. The HTM on Iceland occurred a bit later, 8–6 ka, whereas the onset on Svalbard was 10.8 ka. The latest general HTM onset (7–4 ka) was in central Canada. Most regions registered the onset of summer cooling by 6–5 ka. The average summer temperature anomaly during the HTM across the western Arctic was 1.6 °C, although it ranged from 0.5 to 3.0 °C, with the largest changes in the North Atlantic sector and the smallest over North Pacific sector.

The spatial pattern of HTM onset can be explained in part by regional variations in the proximity to continental ice sheets, which depressed temperatures nearby until the ice melted back, and to changes in freshwater delivery to the North Atlantic, which influenced the strength of the Atlantic meridional circulation.

Sea-ice conditions in the Arctic Ocean and adjacent channels have been developed by from a wide array of key proxies including the remains of whales and walrus, warm-water marine mollusks, changes in microfaunal assemblages, especially diatoms and dinoflagellate cysts, and more recently using biomarkers diagnostic of sea-ice or sea-ice-free organisms

(Polyak et al., 2010). These reconstructions parallel the terrestrial record for the most part. They demonstrate that an increased mass of warm Atlantic water moved into the Arctic Ocean at about the beginning of the Holocene. An obligate Atlantic-water mollusk appeared on northern Svalbard by 10.6 ka, with peak penetration of Atlantic water between 9.3 and 8 ka (Salvigsen, 2002), with most thermophilous mollusks disappearing from Svalbard by ~5 ka. Dates on the flooding of Bering Strait range from ~12 ka to slightly before 13 ka, although precise dating remains dependent on knowledge of the marine reservoir age at that time. The influx of Pacific water to the Arctic Ocean peaked between 9 and 5 ka, then diminished through the late Holocene. The extra ocean heat from both Atlantic and Pacific sources, coupled with increased summer insolation, decreased the area of perennial sea-ice cover during the early Holocene. Decreased sea-ice cover in the western Arctic also may be indicated by changes in concentrations of sea-salt sodium in the Penny Ice Cap, eastern Canadian Arctic, and the Greenland Ice Sheet.

As summer temperatures increased through the early Holocene, North American treeline expanded northward into regions formerly mantled by tundra, although the northward extent appears to have been limited to perhaps a few tens of kilometers beyond its recent position. In contrast, some tree-line species expanded well beyond their current limits in the Eurasian Arctic. Dated macrofossils indicate that individuals of the tree genera *Betula* (birch) and *Larix* (larch) lived far north of the modern treeline across most of northern Eurasia between 11 and 10 ka, and *Larix* extended beyond its modern limits as early as 13–12 ka in eastern Siberia (Binney et al., 2009, and references therein). In the Taimyr Peninsula of Siberia and nearby regions the most northerly limit reached by trees during the Holocene was more than 200 km north of the current treeline. Spruce (*Picea*) advanced slightly later than the other two genera. Interestingly, pine (*Pinus*), which now forms the conifer treeline in Fennoscandia and the Kola Peninsula of Russia, does not appear to have established appreciable forest cover at or beyond the present treeline in the Kola Peninsula until around 7 ka. However, quantitative reconstructions of temperature suggest that summer temperatures were above modern by 9 ka, and the development of extensive pine cover at and north of the present treeline appears to have been delayed relative to this warming. Treeline began to retreat southward across northern Eurasia 3–4 ka (Binney et al., 2009).

The timing of the HTM in the Eurasian Arctic overlaps the widest expression of the HTM in the western Arctic, but the timing of onset and termination in Eurasia shows less variability than in North America, and the magnitude of the treeline expansion and retreat is greater in the Eurasian Arctic.

Permafrost was degraded across much of the Russian Arctic during the HTM. Melting permafrost was widespread in the European north, but across Siberia permafrost partially thawed locally (reviewed by Astakhov, 1995). Areas south of the Arctic Circle appear to have experienced deep thawing (100–200 m depth) through the HTM, followed by renewed permafrost expansion after 3 ka.

Quantitative estimates of HTM summer temperature anomalies along the northern margins of Eurasia and adjacent islands range from 1 to 3 °C. Sea-surface temperature anomalies

during the HTM were as much as 4–5 °C for the eastern North Atlantic sector and adjacent Arctic Ocean.

Neoglaciation

Many climate proxies are available to characterize the overall pattern of late Holocene climate change. Although the timing of the HTM around the Arctic is at least partially modulated by the waning continental ice sheets, the last substantial ice-sheet-dominated climate perturbation was the brief cold excursion about 8.2 ka. By 8 ka the rapidly receding continental ice sheets had become small enough that they no longer exerted a strong influence on regional climates, and most proxy summer temperature records from the Arctic indicate an overall cooling trend through the late Holocene, as orbital influences steadily reduced summer insolation across the Northern Hemisphere.

The least ambiguous proxies that reflect the overall decrease in Northern Hemisphere summer temperatures through the Holocene are mountain glaciers and ice caps. Widespread evidence for the expansion or regrowth of glaciers after the HTM was summarized by [Porter and Denton \(1967\)](#), who introduced the term Neoglaciation to describe this reversal of the long deglaciation following the LGM. Although the timing of the onset of Neoglaciation across the Arctic is poorly constrained, most regions show evidence of initial glacier expansion or regrowth between 6 and 5 ka. Throughout the Holocene glacier mass balance has been dominantly controlled by summer temperature ([Koerner, 2005](#)), and the expansion of glaciers throughout the Arctic is interpreted to reflect a decrease in summer temperatures.

Neoglacial summer cooling is supported by several other lines of evidence: a reduction in melt layers in the Agassiz Ice Cap ([Koerner and Fisher, 1990](#)), and the decrease in $\delta^{18}\text{O}$ values in ice cores across Greenland and Arctic Canada ([Vinther et al., 2009](#)), clear patterns of change in borehole thermometry through the Greenland Ice Sheet; the retreat of large marine mammals and warm-water-dependent mollusks from the Canadian Arctic; the southward migration of the northern treeline across central Canada, Eurasia, and Scandinavia ([Barnekow and Sandgren, 2001](#)); the expansion of sea-ice cover along the shores of the Arctic Ocean on Ellesmere Island, in Baffin Bay, and in the Bering Sea; and the shift in vegetation communities inferred from plant macrofossils and pollen around the Arctic, including Wrangel Island ([Lozhkin et al., 2001](#)). The assemblage of microfossils and the stable isotope ratios of Foraminifera in marine sediment indicate a shift toward colder, lower salinity sea-surface conditions about 5 ka along the East Greenland Shelf ([Jennings et al., 2002](#)) and the western Nordic seas ([Koç and Jansen, 1994](#)), suggesting an increased flux of sea ice from the Arctic Ocean. Where quantitative estimates of temperature change are available, they generally indicate that summer temperature decreased by 1–2 °C during this initial phase of cooling.

Climate of the Past 2 ka

Climate reconstructions of the past 2 ka have gained increased attention because they provide a background reference for the range of natural variability against which changes that might be tied to anthropogenic activities can be compared. For most

of the Arctic, the pattern of overall summer cooling following an early HTM forms a multimillennial trend that culminated in the cold Little Ice Age (LIA) of the thirteenth through nineteenth centuries. Most Arctic glaciers and ice caps reached their maximum dimensions of the past 8 ka during the LIA ([Miller et al., 2010a](#)). High-resolution Arctic climate reconstructions for the first millennium AD are relative rare. The pan-Arctic (to 60° N latitude) compilation of [Kaufman et al. \(2009\)](#) included 23 proxy temperature records from lake sediments, tree rings, and glacier ice that extend back at least 1000 years are resolved at annual to subdecadal scale. The composite reconstruction is consistent with other evidence for millennial-scale trend of overall summer cooling since the HTM.

Warmth during Medieval times was initially recognized from evidence in Western Europe ([Lamb, 1977](#)), but the term is commonly applied to other regions over a wide temporal range. We restrict our consideration of Medieval warmth to the period between AD 950 and 1250. The strongest evidence for Medieval warmth comes from the northern North Atlantic region, where there is growing evidence for an episode of relatively cold summers between ~AD 600 and 950, followed by three centuries of relatively warmer summers during Medieval times. Evidence for warmth during this interval is based on reductions in glacier and ice cap dimensions, faunal changes in marine sediment, speleothems, ice cores, borehole temperatures, tree rings, and archaeology. Western Greenland ([Crowley and Lowery, 2000](#)), the Greenland Ice Sheet ([Dahl-Jensen et al., 1998](#)), Swedish Lapland ([Grudd et al., 2002](#)), northern Siberia ([Naurzbaev et al., 2002](#)), Arctic Canada ([Anderson et al., 2008](#)), and Iceland ([Geirsdóttir et al., 2009](#); [Larsen et al., 2011](#)) were all relatively warm around AD 1000. During Medieval time, Inuit populations moved out of Alaska into the eastern Canadian Arctic and hunted whale from skin boats in regions perennially ice-covered in the twentieth century ([McGhee, 2004](#)).

Medieval warmth is generally ascribed to a reduction in sulfate aerosols derived from explosive volcanism ([Jansen et al., 2007](#)), with the extra warmth around the North Atlantic and adjacent regions possibly linked to changes in oceanic circulation as well ([Broecker, 2001](#)).

The Arctic-wide reconstruction of [Kaufman et al. \(2009\)](#) indicates that average summer temperatures were similar to or higher than the warmest interval of the middle ages during much of the first half of the first millennium AD. Following the sixth century and prior to the twentieth, the average warmest interval occurred between AD 940 and 970. Only some sites registered peak preindustrial temperatures during this interval, however. The high average temperature in the composite record during Medieval time is dominated by sites in the northwestern North Atlantic sector (Greenland and Canadian High Arctic), especially isotope records from glacier ice. Indications of Medieval warmth outside the North Atlantic sector include the retreat of glaciers in southeastern Alaska ([Reyes et al., 2006](#); [Wiles et al., 2008](#)), and the wider tree rings in some high-latitude tree-ring records from Asia and North America ([D'Arrigo et al., 2006](#)). However, [D'Arrigo et al. \(2006\)](#) emphasized the uncertainties involved in estimating Medieval warmth relative to that of the twentieth century, owing in part to the sparse geographic distribution of proxy data as

well as to the less coherent variability of tree-growth temperature estimates. Hughes and Diaz (1994) argued that the Arctic as a whole was not anomalously warm throughout Medieval time.

Given the importance of understanding climate of the most recent past and the richness of the available evidence, intensive scientific effort has resulted in numerous Northern Hemisphere average temperature reconstructions for the past millennium (Mann et al., 2008, and references therein). These reconstructions are based on annually resolved proxy records, primarily from tree rings, with additional records from Greenland ice cores and a few annually laminated lake sediment records. Decadally resolved proxy temperature records from the Arctic (poleward of 60° N), primarily from lake sediments, have been explored for comparison (Kaufman et al., 2009, and references therein). In general, the Northern Hemisphere and the Arctic average temperature records are broadly similar: they show modest summer warmth during Medieval times, a variable, but colder climate from about AD 1250 to 1850, followed by twentieth century warming as shown by both paleoclimate proxies and the instrumental record. Less is known about changes in precipitation, which is spatially and temporally more variable than temperature.

The trend toward colder summers after ~AD 1250 coincides with the onset of the LIA, which persisted until ~AD 1850, although the timing and magnitude of specific cold intervals exhibit regional variability. The climate history of the LIA has been extensively studied in natural and historical archives, and it is well documented in Europe and North America (Grove, 1988). Historical evidence from the Arctic is relatively sparse, but it generally agrees with historical records from northwest Europe. Arctic proxy climate records from glacial and nonglacial sources show that the coldest interval of the Holocene occurred between ~AD 1450 and ~AD 1850, and during this interval most glaciers reached their Neoglacial maximum. Recent evidence from the Canadian Arctic indicates that, following substantial ice recession in Medieval times, glaciers and ice caps began to expand abruptly in the second half of the thirteenth century, and that ice expansion was further amplified ~AD 1450, after which ice caps receded to their pre-LIA margins only in recent decades (Miller et al., 2011).

The average summer temperature of the Northern Hemisphere during the LIA was no more than 1 °C lower than the twentieth century average (Mann et al., 2008), but was substantially greater in some regions. LIA cooling appears to have been stronger in the Atlantic sector of the Arctic than in the Pacific (Kaufman et al., 2004), perhaps because explosive volcanism promoted the development or transport of sea ice into the North Atlantic, leading to a reduction in the Atlantic meridional overturning circulation, which further amplified LIA cooling there (Miller et al., 2011). Although the initiation of the LIA and the structure of climate fluctuations during this multicentennial interval vary around the Arctic, most records show warming beginning in the late nineteenth century (Kaufman et al., 2009; Overpeck et al., 1997). The end of the LIA was apparently more uniform both spatially and temporally than its initiation.

Summer cooling that marks the transition into the LIA was in part a consequence of the Holocene-long decrease in Northern Hemisphere summer insolation due to the orbital changes

described earlier, and triggered by increased explosive volcanism in the late thirteenth and fifteenth centuries. This transition was likely aided by decreased solar irradiance at these times, and amplified by strong positive feedbacks, especially expanded Arctic Ocean sea ice and terrestrial snow cover, possibly enhanced by a weakening of the meridional circulation in the northern North Atlantic.

Placing Twentieth Century Arctic Warming in a Millennial Perspective

Much scientific effort has been devoted to learning how twentieth and early twenty-first century warmth compares with warmth during earlier times (e.g., Jansen et al., 2007). A data-model comparison indicates that the long-term cooling trend that dominated in the Arctic during the past nineteen centuries was linked to decreasing summer insolation from orbital factors, and that this trend was reversed during the twentieth century, despite continued reduction of summer insolation across the Arctic (Kaufman et al., 2009). Owing to the orbital changes affecting midsummer insolation (a drop in June insolation of about 1 W m⁻² at 75° N and 2 W m⁻² at 90° N during the last millennium; Berger and Loutre, 1991), additional forcing is required to explain why summer temperatures in recent decades have been similar to, and in most regions warmer than, summer temperatures achieved in Medieval times.

Thin, cold ice caps in the eastern Canadian Arctic preserve rooted vegetation beneath them that was killed by the expanding ice cover. A recent compilation of 94 ¹⁴C-dated plant samples recently emerged from beneath receding ice caps on northern Baffin Island shows that many of the ice caps that formed >1700 years ago persisted through Medieval times before melting early in the twenty-first century (Miller et al., 2011).

Records of surface melting from ice caps offer another view by which twentieth century warmth can be placed in a millennial perspective. The longest record comes from the Agassiz Ice Cap in the Canadian High Arctic, for which the percentage of summer melting of each season's snowfall is reconstructed for the past 10 ka. The percent of melt follows the general trend of decreasing summer insolation from orbital changes, but some brief departures are substantial. Of particular note is the significant increase in melt percentage during the past century; current percentages are higher than any other melt intensity since at least 4000 years ago (Fisher et al., 2011).

Changes in lake sediments and their biota record help place the recent century in a longer perspective. Extensive biotic changes, especially in the post AD 1850 interval, are interpreted to reflect recent warming above the Medieval warmth on Ellesmere Island and probably in other regions, although alternative explanations have been debated and explored (Smol and Douglas, 2007; Smol et al., 2005). D'Arrigo et al. (2006) show tree-ring evidence from a few North American and Eurasian sites that imply that summers were cooler in the Medieval Warm Period than in the late twentieth century, although the statistical confidence is weak. Tree-ring and tree-line studies in western Siberia (Esper and Schweingruber, 2004) and Alaska (Jacoby and D'Arrigo, 1995) suggest that

warming since 1970 has enhanced tree growth and follows a circumpolar trend. [Hantemirov and Shiyatov \(2002\)](#) present records from the Yamal Peninsula, Russia, well north of the Arctic Circle, showing summer temperatures of recent decades are the most favorable for tree growth within the past 4 ka.

The [National Research Council \(2006, p. 3\)](#) evaluated the available published data on globally and hemispherically averaged temperatures for the last millennium, and found that “Presently available proxy evidence indicates that temperatures at many, but not all, individual locations were higher during the past 25 years than during any period of comparable length since A.D. 900.” Greater uncertainties for hemispheric or global reconstructions were identified in assessing older comparisons. Climate models are unable to reproduce the observed warmth of the late twentieth century unless recent increases in greenhouse gases due to anthropogenic fossil fuel combustion are included, lending credibility to the argument that late twentieth century warmth is dominantly an artifact of human activities.

Conclusions

As the planet cooled from peak warmth in the early Cenozoic, extensive Northern Hemisphere ice sheets developed by 2.6 Ma, leading to changes in the circulation of both the atmosphere and oceans. From ~2.6 to ~1.0 Ma, ice sheets came and went about every 41 ka, in pace with cycles in the tilt of Earth’s axis, but for the past 700 ka, glacial cycles have been longer, lasting ~100 ka, separated by brief, warm interglaciations, when sea level and ice volumes were close to present. The cause of the shift from 41 to 100 ka glacial cycles is still debated. During the penultimate interglaciation, ~130 to ~120 ka, solar energy in summer in the Arctic was greater than at any time subsequently. As a consequence, Arctic summers were ~5 °C warmer than at present, and almost all Arctic glaciers melted completely except for the Greenland Ice Sheet, and even it was reduced in size substantially from its present extent. With the loss of land ice, sea level was ~5 m higher than present, with the extra melt coming from both Greenland and Antarctica, as well as small glaciers and ice caps. The LGM peaked ~21 ka, when mean annual temperatures over parts of the Arctic were as much as 20 °C lower than at present. Ice recession was well underway 16 ka; by 8 ka even the Laurentide Ice Sheet was too small to have a strong influence on the climate system, and most of the Northern Hemisphere ice sheets had melted by 6 ka. Insolation reached a summer maximum (9% higher than at present) ~11 ka and has been decreasing since then, primarily in response to the precession of the equinoxes. The extra energy elevated early Holocene summer temperatures throughout the Arctic 1–3 °C above twentieth century averages, enough to completely melt many small glaciers throughout the Arctic, although the Greenland Ice Sheet was only slightly smaller than at present. Early Holocene summer sea-ice limits were substantially smaller than their twentieth century average, and the flow of Atlantic water into the Arctic Ocean was substantially greater. As summer solar energy decreased in the second half of the Holocene, glaciers became re-established or advanced, sea ice expanded, and the flow of warm Atlantic water into the Arctic Ocean

diminished. Late Holocene cooling reached its nadir during the LIA (~AD 1250 to ~AD 1850), when sun-blocking aerosols from volcanic eruptions and perhaps other causes added to the orbital cooling, allowing most Arctic glaciers to reach their maximum Holocene extent. During the warming of the past century, glaciers have receded throughout the Arctic, terrestrial ecosystems have advanced northward, and perennial Arctic Ocean sea ice has diminished, with the most pronounced pan-Arctic changes occurring since AD 1970.

The histories of temperature and precipitation across Arctic lands during the Cenozoic exhibit clearly defined broad trends despite the limitations caused by scattered, and incomplete records. Arctic climate proxies for the most part reflect summer temperature anomalies, although ice-core isotopes reflect influences from changes in mean annual temperatures, moisture source area, and seasonality of precipitation. Precipitation changes in the past are more difficult to reconstruct than are paleotemperatures, in part due to the greater spatial variability of precipitation, but also due to the weak correlation between most proxies and precipitation amount. Nevertheless, some broad patterns clearly emerge.

On all time scales through the Cenozoic, temperature changes have been greater in the Arctic than for the Northern Hemisphere as a whole, for both summer and annual mean changes. This greater sensitivity reflects the powerful positive feedbacks acting across the Arctic that amplify changes due to external forcings. The strongest feedback on short timescales (decadal to millennial) is the expansion and contraction of sea ice, with additional positive feedbacks from changing seasonal snowcover, changing distribution of forest and tundra ecosystem boundaries, growth and decay of permafrost, and changes in the strength of the ocean’s meridional overturning circulation. On longer timescales (multimillennial), changes in the location and rate of deep convection in the North Atlantic, and the growth and decay of continental ice sheets are particularly important feedbacks, through changes in energy transfer, CO₂ and other greenhouse gas budgets, albedo, and ice-sheet height, and to a lesser extent, a negative feedback resulting from isostatic compensation to the increased ice load that lowers the ice surface. Accompanying changes in sea-surface temperatures control the amount of water vapor released to the atmosphere, influencing the magnitude of the greenhouse effect.

The great temperature reduction across the Arctic during glaciations increased the pole-to-equator thermal gradient, increasing planetary wind speeds, and the Arctic cold was amplified globally by reduced atmospheric water vapor and CO₂, the two most important greenhouse gases. Reduced atmospheric water vapor resulted in globally drier and dustier conditions on average, and ice sheet instabilities had dramatic impacts on the oceanic meridional overturning circulation, both with global consequences.

The primary forcing that explains the first-order climate trends through the Cenozoic has been the generally steady decrease in greenhouse gases in the atmosphere (with some notable perturbations) that produced a first-order temperature decline through most of the Cenozoic. Although this temperature decline continued through the Quaternary, high frequency temperature variations across the Arctic were superimposed on the gradual cooling trend, tied to the growth

and decay of the large continental ice sheets. Throughout the Quaternary, changes in the seasonal and geographic distribution of insolation caused by well-known oscillations in Earth's orbital parameters, primarily axial tilt (obliquity) and precession of the equinoxes, have paced the expansion and retreat of Northern Hemisphere ice sheets, with global climate consequences. Arctic Quaternary climates have also responded to variations in greenhouse gas forcings on glacial-interglacial timescales. During the Holocene, the general decrease in summer temperatures across the Arctic have been driven by precession, with perturbations to the millennial-scale cooling trend resulting from changes in the frequency of sulfur-rich explosive volcanic eruptions, and to small changes in solar luminosity. The strong warming trend over the past century across the Arctic, and since ~1970 in particular, stands in stark contrast to the first-order middle and late Holocene cooling trend, and is very likely a result of increased greenhouse gases that are a direct consequence of anthropogenic activities.

Acknowledgments

This paper is an outgrowth of a series of syntheses commissioned by the US Global Change Research Program that was focused on paleoclimate of the Arctic. Modified versions of these reports were published as a series of five papers in *Quaternary Science Reviews* in 2010. This paper is based on one of those papers, "Temperature and precipitation history of the Arctic" (Miller et al., 2010a), from which it has been condensed and revised to include new results since the original synthesis was compiled. A wide range of national funding agencies and logistical support units have supported the research from which the reported paleoclimate reconstructions were derived. The following authors each acknowledge at least partial support from the United States National Science Foundation as follows: GHM, grants ARC 0714074 and ATM-0318479; RBA, grants 0531211 and 0424589; JWCW, grants 0806387, 0537593, and 0519512; LP, grants ARC-0612473 and ARC-0806999; LDH, grant OPP-0652838; DSK, grant ARC-0455043; MCS, grants ARC-0531040, ARC-0531302. MSVD, JPS, and APW collectively acknowledge financial support through grants from the Canadian Natural Sciences and Engineering Research Council. Critical logistical support has been provided by the Canadian Polar Continental Shelf Project, the NSF Office of Polar Programs, and the Icelandic Center for Research as well as other national bodies.

The Younger Dryas Climate Event

A E Carlson, University of Wisconsin, Madison, WI, USA

© 2013 Elsevier B.V. All rights reserved.

Introduction

The Younger Dryas has long been viewed as the canonical abrupt climate change event. The name is derived from the late 1800s Swedish and Danish pollen records that indicated a return of the cold-tolerant plant *Dryas octopetala* following a warm interval (the Allerød warm period) (Andersson, 1896; Hartz and Milthers, 1901). The advent of radiocarbon dating techniques constrained this European cooling event to ~11–10 ka (ka: 1000 years ago) in radiocarbon years (Mangerud et al., 1974) or ~12.9–11.7 ka in calendar years (Rasmussen et al., 2006). At this time, boreal summer insolation (the driving force behind deglaciation) neared its peak (Figure 1(a)) and the sea level was approximately halfway through its deglacial rise of 120–130 m (Figure 1(e)). Subsequent research identified climate changes correlative to the European Younger Dryas in the North Atlantic and North Pacific Oceans, across Asia and North America, and in the tropics (e.g., Clark et al., 2002; Shakun and Carlson, 2010). The footprint of Younger Dryas climate change suggests that it was caused by a reduction in Atlantic meridional overturning circulation (AMOC) (Stouffer et al., 2006), for which there has been growing evidence since the mid-1980s (Boyle and Keigwin, 1987). This article reviews the Younger Dryas climate event, starting with the geographic pattern of climate change, followed by a discussion of ocean circulation changes, and ending with its ultimate forcing.

Extent of the Younger Dryas

The Northern Hemisphere Younger Dryas

Greenland ice cores

In the Northern Hemisphere, Greenland ice cores provide the best expression of the Younger Dryas as a cold event. Ice core $\delta^{18}\text{O}$ (δ signifies a change in isotopic ratio relative to a standard multiplied by 1000) consistently decreases by ~3‰ with an ~3.5‰ increase at the end of the event, reflecting up to 9 °C of cooling and 11 °C of warming (Figure 1(b)) (Alley, 2000). Isotopic ratios of nitrogen and argon gases from the GISP2 (Greenland Ice Sheet Project 2) ice core suggest 10 ± 4 °C of warming at the end of the Younger Dryas (Grachev and Severinghaus, 2005). The $\delta^{18}\text{O}$ records could also have an imprint of precipitation source change because Greenland Ice Sheet accumulation decreased by ~40% (0.11–0.07 m year⁻¹) (Figure 1(c)) and dust records suggest atmospheric reorganization in only several decades (Alley, 2000). Greenland deuterium excess, a proxy of precipitation source, shifted in 1–3 years at the start of the Younger Dryas, suggesting that 2–4 °C of source cooling was imprinted on the isotopic records (Steffensen et al., 2008). The trapped nitrogen isotopes also indicate that high-altitude Greenland was ~15 °C colder than present, but this estimate should not be extended to the ice

margins as it may reflect a strengthening of the near-surface atmospheric inversion that is common over ice sheets (Severinghaus et al., 1998). Indeed, east Greenland valley glacier records suggest that summers were only 6–7 °C cooler than present (Kelly et al., 2008). Greenland runoff to the ocean was also enhanced (Figure 1(d)) (Carlson et al., 2008b) with mild terrestrial and marine summer conditions (Björck et al., 2002; Williams, 1993) during the Younger Dryas.

Europe

European pollen, chironomid, lake $\delta^{18}\text{O}$, and speleothem records indicate that a cooler (2–6 °C) and/or drier climate characterized the Younger Dryas, which potentially changed in decades (Figure 2(a) and 2(b)); e.g., Brauer et al., 1999; Genty et al., 2006; Heiri et al., 2007; von Grafenstein et al., 1999). Mountain glaciers readvanced in the Swiss Alps implying 3–4 °C of cooling (e.g., Ivy-Ochs et al., 2009). The Scandinavian Ice Sheet also readvanced, depositing an extensive moraine system across southern Norway, Sweden, and Finland (Andersen et al., 1995). Records from glacially influenced lakes in western Norway show an increase in glacier activity (Nesje, 2009), and the Iceland Ice Cap halted retreat during the Younger Dryas (Licciardi et al., 2007).

North Atlantic records

In the eastern North Atlantic, Iberian Margin and Mediterranean sea surface temperature (SST) records show 1–3 °C of cooling (Figure 2(d)) (e.g., Bard et al., 2000; Cacho et al., 2001). Northward up to the Norwegian Sea, SST records indicate 1–7 °C of cooling (Figure 2(c)) (e.g., Benway et al., 2010; Chapman and Maslin, 1999; Dolven et al., 2002; Ebbesen and Hald, 2004; Karpuz and Jansen, 1992). Westward, SSTs cooled by 1–2 °C in the subtropical gyre (Carlson et al., 2008a; Chapman and Maslin, 1999) and by 5–10 °C near maritime Canada (de Vernal et al., 1996; Keigwin and Jones, 1995). In contrast, SST increased by ~1.5 °C near southeastern United States (Figure 2(e)), which was related to the slowing of AMOC and decreased northward heat transport (Carlson et al., 2008a). The Gulf of Mexico also cooled slightly near the end of the Younger Dryas (Figure 2(f)) (Flower et al., 2004).

North America

Pollen, lake $\delta^{18}\text{O}$, and soil $\delta^{13}\text{C}$ records from maritime Canada to north-central United States suggest a cooler and drier Younger Dryas (e.g., Dorale et al., 2010; Shuman et al., 2005; Yu and Eicher, 1998). In the southeastern United States, however, the Younger Dryas is characterized by a warmer and/or wetter climate, reflecting the trapping of heat in the western subtropical gyre due to reduced AMOC (Grimm et al., 2006). The Pacific Coast of the United States and Canada experienced 2–3 °C of Younger Dryas cooling (Figure 3(a) and 3(b)) and a wetter climate (e.g., Barron et al., 2003; Kaufman et al., 2010; Kienast and McKay, 2001; MacDonald et al., 2008; Mathewes

Figure 1 Greenland. (a) June insolation at 65°N (Berger and Loutre, 1991). (b) Greenland ice core $\delta^{18}\text{O}$ (red = GISP2 (Greenland Ice Sheet Project 2), blue = GRIP (Greenland Ice Core Project), green = NGRIP (North Greenland Ice Core Project); left) (Rasmussen et al., 2006) and GISP2 temperature (black; right) (Alley, 2000). (c) GISP2 ice core accumulation rate (Alley, 2000). (d) Ti concentration record off southern Greenland (Carlson et al., 2008b). (e) Relative sea-level data (Clark et al., 2009). Gray bar on this and other figures indicates timing of the Younger Dryas.

et al., 1993; Sea and Whitlock, 1995; Vacco et al., 2005). In the North American southwest, packrat midden $\delta^{13}\text{C}$ temperature reconstructions imply $>3^\circ\text{C}$ of cooling (Cole and Arundel, 2005), and lake, speleothem, and water table records suggest an increase in net precipitation during the Younger Dryas (Figure 3(c) and 3(d)) (Asmerom et al., 2010; Benson et al., 1997; Pigati et al., 2009; Polyack et al., 2004; Wagner et al., 2010). Valley glaciers readvanced or reoccupied cirques in many of the mountain ranges of the North American Cordillera (e.g., Davis et al., 2009). The southern margin of the Laurentide Ice Sheet also readvanced, depositing a moraine from western Lake Superior to southeastern Quebec (Lowell et al., 1999), with its northwest margin in Hudson Strait increasing iceberg discharge during the Younger Dryas (Andrews and Tedesco, 1992).

North Africa and the Middle East

In North Africa, climate cooled and net precipitation decreased during the Younger Dryas. A record of terrigenous input off the coast of northwest Africa indicates an increase in dust during the Younger Dryas, implying drying of the Sahara Desert (Figure 4(a)) (deMenocal et al., 2000), which is consistent

Figure 2 Europe and North Atlantic. (a) German lake $\delta^{18}\text{O}$ (von Grafenstein et al., 1999). (b) French speleothem $\delta^{18}\text{O}$ (Genty et al., 2006). with speleothems from North Africa and the Middle East (Figure 4(b)) (e.g., Genty et al., 2006; Shakun et al., 2007). This precipitation decrease is attributable to the southward shift in the Intertropical Convergence Zone (ITCZ) in response to reduced AMOC and North Atlantic cooling (Stouffer et al., 2006). Reduced upwelling in the Arabian Sea because of decreased winds is also consistent with southward ITCZ migration (Altabet et al., 2002; Schulz et al., 1998). North African SSTs cooled $0.5\text{--}1^\circ\text{C}$ (deMenocal et al., 2000; Zhao et al., 1995), but Arabian SSTs were relatively constant during the Younger Dryas (Saher et al., 2007).

Asia

Large portions of central to northern Asia currently lack paleoclimate records spanning the Younger Dryas interval. Nevertheless, a decrease in $\delta^{18}\text{O}$ from Lake Baikal in southern Russia implies shifts in moisture sources to the lake and potential cooling during the Younger Dryas (Morley et al., 2005). Further east, a pollen record from central Japan suggests $\leq 3^\circ\text{C}$ of cooling during the Younger Dryas (Nakagawa et al., 2003), whereas SST records from the China Sea indicate $0.5\text{--}1^\circ\text{C}$ of cooling (Kubota et al., 2010; Sun et al., 2005). Multiple

et al., 2001), with a south China lake record suggesting an increase in winter Asian monsoon strength during the Younger Dryas (Yancheva et al., 2007). Overall, these paleomonsoon proxies are consistent with a southward shift in the ITCZ.

Tropical Climate and the Younger Dryas

East Atlantic and Central America

The temperature pattern observed in the tropics during the Younger Dryas is complex (Shakun and Carlson, 2010). SSTs show a warming of 0.25–1.2 °C in the Caribbean Sea and off northeast Brazil (Jaeschke et al., 2007; Rühleman et al., 1999; Schmidt et al., 2004; Weldeab et al., 2006), but a cooling of ~3.3 °C north of Venezuela (Figure 5(a)) (Lea et al., 2003), possibly from a southward shift in the ITCZ that increased trade wind strength and upwelling (Hughen et al., 1996). Indeed, precipitation proxies suggest that precipitation decreased north of the equator and increased south of the equator (Haug et al., 2001; Jaeschke et al., 2007; Wang et al., 2007). Ice cores from Peru and Bolivia show an ~2‰ decrease in $\delta^{18}\text{O}$ (Thompson et al., 1998), concurrent with higher lake levels in nearby Lake Titicaca and consistent with southward ITCZ migration (Baker et al., 2001). Despite wetter conditions, a warmer climate would explain glacier recession in Peru during the Younger Dryas (Rodbell and Seltzer, 2000).

West Atlantic and Africa

Off tropical West Africa, SST records indicate ~0.2 °C of warming during the Younger Dryas (Shefuß et al., 2005; Weldeab

et al., 2007) in agreement with air temperature proxies that suggest $\sim 0.8^\circ\text{C}$ of warming (Weijers et al., 2007). Another Younger Dryas SST record from southwestern tropical Africa, however, suggests a slight cooling from increased winds and an enhanced local upwelling of colder waters (Kim et al., 2002), which may extend to $\sim 25^\circ\text{S}$ (Farmer et al., 2005). Eastern tropical Africa temperature records indicate a complex pattern with warming at Lake Tanganyika (Figure 5(c)) and potential cooling at Lake Malawi and surrounding regions (Gasse et al., 2008; Tierney et al., 2008; Weldeab et al., 2007). Off the southeast coast of Africa near Madagascar, SSTs warmed during the Younger Dryas (Levi et al., 2007). Interestingly, despite evidence for a southward shift in the ITCZ in tropical Africa (e.g., Gasse et al., 2008; Johnson et al., 2002; Tierney and Russell, 2007), leaf wax $\delta^{13}\text{C}$ from Lakes Malawi and Tanganyika indicate arid conditions, highlighting a complex tropical African climate response to reduced AMOC (Castaneda et al., 2007; Tierney et al., 2008).

Tropical Pacific

In the eastern tropical Pacific, most SST records indicate little temperature change or slight warming during the Younger Dryas (Figure 5(b)) (e.g., Benway et al., 2006; Lea et al., 2006), with one record showing $\sim 0.4^\circ\text{C}$ of cooling (Kienast et al., 2006). Paleosalinity reconstructions suggest a net decrease in moisture transport from the Atlantic to the Pacific because of a southward displacement of the ITCZ (Benway et al., 2006). Further west, the Mauna Kea Ice Cap of the Hawaiian Islands may have readvanced during the Younger Dryas from a southward shift in the ITCZ, with enhanced extratropical storms and northward local winds that transported more moisture to Hawaii (Anslow et al., 2010). In the tropical west Pacific, SSTs generally warmed but with regions of cooling potentially reflecting proxy biases (Figure 5(d)) (Kienast et al., 2001; Levi et al., 2007; Linsley et al., 2010; Rosenthal et al., 2003; Stott et al., 2007).

Southern Hemisphere Climate During the Younger Dryas

During the Younger Dryas, the extratropical Southern Hemisphere generally warmed (Shakun and Carlson, 2010). Antarctic ice cores record increasing $\delta^{18}\text{O}$ and δD (Figure 6(e) and 6(f)) (e.g., Blunier and Brook, 2001; EPICA Community Members, 2006; Jouzel et al., 2007). SST records show a warming of $0.3\text{--}1.9^\circ\text{C}$ from the southeast Atlantic to New Zealand (Figure 6(a)–6(c)) (Barker et al., 2009; Barrows et al., 2007; Carlson et al., 2008b; Lamy et al., 2004; Pahnke and Sachs, 2006). Speleothem and pollen records from New Zealand and pollen records from South America confirm that the Younger Dryas was generally a period of warming (e.g., Hajdas et al., 2003; Moreno et al., 2009; Newnham and Lowe, 2000; Turney et al., 2003; Williams et al., 2005), consistent with New Zealand and Patagonian glacier retreat (Kaplan et al., 2008; 2010; Moreno et al., 2009; Putnam et al., 2010).

Geographic Response Summary

Globally, the Younger Dryas was a period of climate change. Plotting Younger Dryas temperature and climate anomalies against latitude shows that climate anomalies increased in magnitude toward the poles with opposite signs in the

Figure 6 Southern Hemisphere. (a) Mg/Ca-SST near southeast Brazil (Carlson et al., 2008a). (b) Alkenone-SST near southern Chile (Lamy et al., 2004). (c) Alkenone-SST near New Zealand (Pahnke and Sachs, 2006). (d) Atmospheric CO_2 (Monnin et al., 2001). (e) Antarctic Dome C change in temperature (Jouzel et al., 2007). (f) Antarctic EDML ice core $\delta^{18}\text{O}$ (EPICA Community Members, 2006).

Northern and Southern Hemispheres (Figure 7) (Shakun and Carlson, 2010), reflecting the bipolar seesaw response (Blunier and Brook, 2001). Nevertheless, greater cooling at high northern latitudes than warming at high southern latitudes results in a net global cooling of $\sim 0.6^\circ\text{C}$ likely caused by more extensive snow and sea-ice cover increasing Northern Hemisphere albedo during the Younger Dryas (Shakun and Carlson, 2010).

Ocean Circulation During the Younger Dryas

The first evidence for a change in AMOC during the Younger Dryas came from North Atlantic proxies of water mass nutrients (benthic $\delta^{13}\text{C}$ and Cd/Ca) that showed that Southern Ocean Deep-water volume increased in the North Atlantic at the expense of North Atlantic Deep-water (Figure 8(b) and 8(c)) (Boyle and Keigwin, 1987). More recently, a proxy of water export ($^{231}\text{Pa}/^{230}\text{Th}$ in marine sediments) from the North Atlantic suggests a $\sim 30\%$ reduction in deep AMOC strength during the Younger Dryas (Figure 8(a)) (McManus et al., 2004), consistent with a reduction in the North Atlantic bottom water currents (Figure 8(d)) (Praetorius et al., 2008). Other tracers of water mass source and age confirm increased Southern Ocean Deep-water and Antarctic Intermediate-water and reduced North Atlantic Deep-water volume

Figure 7 Latitudinal plots of the change in temperature between the Younger Dryas and Allerød (a) and the magnitude of Younger Dryas climate change relative to the glacial-interglacial change in a proxy record (b). Data from Shakun and Carlson (2010).

(Pahnke et al., 2008; Roberts et al., 2010; Robinson et al., 2005). The rise in atmospheric CO_2 during the Younger Dryas (Figure 6(d)) implies increased upwelling and degassing of carbon-rich water, evidence for which exists in the Southern Ocean and along Baja California (Anderson et al., 2009; Marchitto et al., 2007). The reduction in AMOC strength during the Younger Dryas provides the causal mechanism for Northern Hemisphere cooling and Southern Hemisphere warming, as well as the southward displacement of the ITCZ. Coupled

atmosphere-ocean climate models consistently simulate a reduction in AMOC and these attendant climate impacts in response to increased freshwater discharge to the North Atlantic (Liu et al., 2009; Meissner and Clark, 2006; Otto-Bliesner and Brady, 2009; Peltier et al., 2006; Stouffer et al., 2006).

The Cause of the Younger Dryas

The forcing of the Younger Dryas was originally inferred to be northward retreat of the southern Laurentide Ice Sheet margin out of the Great Lakes, thereby routing western Canadian Plains freshwater from the Mississippi River to the St. Lawrence River, with the attendant increase in freshwater discharge to the North Atlantic slowing AMOC (Johnson and McClure, 1976; Rooth, 1982). This hypothesis has more recently been questioned based on marine, terrestrial, and ice-sheet model results.

In the St. Lawrence Estuary, planktic $\delta^{18}\text{O}$ records show a 0.5–0.8‰ decrease at the start of the Younger Dryas (de Vernal et al., 1996; Keigwin and Jones, 1995; Keigwin et al., 2005) when $\delta^{18}\text{O}$ increases in the Gulf of Mexico (Figure 9(b)) (e.g., Flower et al., 2004). Concurrent Younger Dryas cooling of 5–10 °C in the St. Lawrence Estuary (de Vernal et al., 1996; Keigwin and Jones, 1995) may have masked a much larger $\delta^{18}\text{O}$ signal associated with eastward freshwater routing (1.8–2.7‰) (Carlson et al., 2007). Four independent geochemical freshwater source and amount proxies and mollusk $\delta^{18}\text{O}$ from the St. Lawrence River and Estuary support the eastward routing of western Canadian Plains freshwater at the start of the Younger Dryas (Figure 9(c) and 9(d)) (Brand and McCarthy, 2005; Carlson et al., 2007; Cronin et al., 2008). Modeling of the geochemical records indicates a base-flow freshwater discharge increase of ~ 0.12 Sv (Sv = Sverdrup, $10^6 \text{ m}^3 \text{ s}^{-1}$) (Carlson et al., 2007), which is sufficient to slow AMOC (Liu et al., 2009; Meissner and Clark, 2006; Otto-Bliesner and Brady, 2009; Peltier et al., 2006; Stouffer et al., 2006). Although dinoflagellate cyst reconstructed sea surface salinity does not decrease, which led de Vernal et al. (1996) to argue that St. Lawrence River freshwater discharge did not

Figure 9 North American runoff records. (a) Two planktic $\delta^{18}\text{O}$ records from the Greenland-Iceland-Norwegian (GIN) Sea (Fram Strait, open symbols; Norwegian Sea, diamonds) (Dokken and Jansen, 1999; Nørgaard-Pedersen et al., 2003). (b) Planktic $\delta^{18}\text{O}$ records from the Gulf of Mexico (Southern Outlet: SO) (purple; Flower et al., 2004) and St. Lawrence Estuary (Eastern Outlet: EO) (blue; Keigwin et al., 2005). (c) Planktic $\delta^{13}\text{C}$ (light green; de Vernal et al., 1996) and $\Delta\text{Mg}/\text{Ca}$ (brown; Carlson et al., 2007). (d) Planktic $^{87}\text{Sr}/^{86}\text{Sr}$ (red) and U/Ca (dark green) from the St. Lawrence Estuary (Carlson et al., 2007).

increase during the Younger Dryas, subsequent research has shown that dinoflagellate cysts are insensitive to salinity changes above 12 practical salinity units (Telford, 2006). Similarly, ^{14}C dates from the eastern outlet of the western Canadian Plains have been interpreted as implying that the eastern outlet was not open until after the start of the Younger Dryas (Lowell et al., 2009). The dates, however, are only minimum limiting and indicate that the eastern outlet was open prior to ~ 12.6 ka, in agreement with the Mississippi and St. Lawrence runoff records (Carlson et al., 2009).

Arguments for a northern routing of western Canadian Plains freshwater and an abrupt discharge of Laurentide meltwater to the north have also been proposed as the forcing of the Younger Dryas. Murton et al. (2010) used optically stimulated luminescence (OSL) ages from sand layers bracketing an erosional surface on the Mackenzie River Delta to argue that the erosional event (e.g., flood) occurred shortly after ~ 13 ka based on the average of the stratigraphically lower dates. However, the OSL ages overlying the erosional surface of ~ 11.9 ka would be a closer age constraint on the erosion event, because erosion removed some unknown amount of sand and the

overlying ages are conformable with the end of the erosion event as flow waned, depositing the sand. Therefore, the erosion event is not related to the onset of the Younger Dryas. Tarasov and Peltier (2005) suggested that a 0.09 Sv discharge of Laurentide meltwater into the Arctic Ocean for 0.3 ka could have forced the Younger Dryas. Climate models do not, however, produce a >1 ka long reduction in AMOC from a 0.3 ka discharge of freshwater (Liu et al., 2009; Meissner and Clark, 2006; Otto-Bliesner and Brady, 2009; Peltier et al., 2006; Stouffer et al., 2006). Although such a melting event could be longer, sea-level records constrain the global meltwater discharge to <5 m of sea-level rise (Figure 1(f)) (Bard et al., 2010) or ~ 0.05 Sv over 1.2 ka. Furthermore, there is no existing paleoceanographic evidence for an increase in freshwater discharge to the Arctic Ocean at the start of the Younger Dryas (Figure 9(a)) (Carlson and Clark, 2008).

Another recent hypothesis for the source of the freshwater that forced the Younger Dryas is a comet that impacted on or near the Laurentide Ice Sheet (Firestone et al., 2007), but evidence for Younger Dryas-like events during earlier deglaciations precludes a unique comet forcing (Carlson, 2008). These earlier events occur at approximately the mid-point of the deglacial sea-level rise, similar to the sea level during the Younger Dryas, suggesting that the AMOC reduction is related to ice-sheet volume/extent (Carlson, 2008). Only continental routing from the Laurentide Ice Sheet retreat pertains to ice-sheet extent/size and the existing records all suggest that this freshwater routing was from the southern outlet to the eastern outlet, consistent with the originally hypothesized forcing of the Younger Dryas.

Introduction

Data–model comparison is the shorthand term used to describe the process of comparing output from climate or Earth-system model simulations of past time periods with paleoenvironmental observations. Such comparisons have two distinct purposes: at a fundamental level, the data–model comparison process leads to an understanding of the mechanisms of past climate and environmental changes; at a practical level, data–model comparisons can be used to evaluate how well state-of-the-art models work.

Paleodata record how environmental conditions have changed in response to changes in climate. However, these data cannot provide an unambiguous explanation of which aspects of the climate have changed or why they have changed. This is because the systems that record past changes are influenced by multiple aspects of the climate and, furthermore, generally display nonlinear responses to changes in specific climate parameters. In addition, the local climate regime itself is governed by multiple controls and a change in regime can be brought about in many different ways. Consequently, there are very many different pathways that could lead to the same response in a paleoclimatic or paleoenvironmental indicator.

To give a concrete example ([Figure 1](#)), pollen records and plant macrofossil data show that the northern treeline (i.e., the limit between tundra and taiga vegetation) was further north than today in Europe and Siberia during the mid-Holocene (ca. 6 ka). The location of the northern treeline is primarily controlled by the accumulated warmth of the growing season (usually expressed in terms of growing degree days, or the number of days with temperature higher than a given threshold multiplied by the temperature of each day). Increased growing season warmth can result from a warmer summer or from higher temperatures in spring and/or autumn resulting in

a longer growing season. Changes in the seasonal distribution of precipitation can also influence the length of the growing season: for example, a reduction in winter and spring snowfall will lead to a more rapid warming in spring and, hence, an earlier onset of the growing season. However, the growth of trees is also controlled by water availability. An increase in precipitation can allow trees to colonize areas from which they were previously excluded. Thus, an observed change in the position of the tundra–taiga boundary could have been caused by changes in many different aspects of the local climate regime. Similarly, the change in the local climate regime could have been brought about in many ways. For example, increased temperature during the growing season could be a response to a change in the seasonal cycle of incoming solar radiation (insolation), or it could result from an increased advection of warm air from adjacent oceans.

Models based on physical principles, or well-documented empirical representations of these physical principles, can provide mechanistic explanations of past climate and environmental changes ([Bartlein and Hostetler, 2004](#)). In order to provide such an explanation, the model must be shown to work under a wide range of different conditions, and it must explicitly include all the relevant components of the system implicated in a particular climate change. Furthermore, the model experiment must be appropriately designed to incorporate the key mechanisms involved. Thus, it would be possible to explore the causes of the northward shift in the tundra–taiga boundary during the mid-Holocene, for example, by using a fully coupled ocean–atmosphere–vegetation model, provided that the model was able to reproduce the position of the northern treeline today and during the mid-Holocene, and provided that the experimental design included factors such as the extent of ice sheets that were not explicitly simulated by the model.

Figure 2 Observed lake levels in northern Africa during the past 18 ka (on the radiocarbon timescale), derived from the Global Lake Status Database, compared to change in runoff (precipitation minus evaporation, $P - E$) simulated by an atmospheric general circulation model (AGCM) driven by changes in orbital forcing and glacial boundary conditions. These simulations and the comparison with observed lake levels were made as part of the COHMAP project and show that observed climate changes in northern Africa during the last glacial–interglacial cycle were caused by orbitally driven changes in the African monsoon. Adapted from Kutzbach JE and Street-Perrott FA (1985) Milankovitch forcing of fluctuations in the level of tropical lakes from 18 to 0 ka BP. *Nature* 317: 130–134.

climate changes could be achieved only through the exercise of global climate models in conjunction with large-scale (preferably global) syntheses of paleoenvironmental data. COHMAP largely focused on pollen and plant macrofossil data of past vegetation changes, and geomorphic and biostratigraphic evidence of past changes in the level or extent of lakes, to provide a picture of regional changes in environmental conditions primarily caused by changes in regional climates.

The most famous example of the COHMAP approach is the now universally accepted explanation for formerly wetter conditions in areas of northern Africa that are desert today (Kutzbach and Street-Perrott, 1985). A wealth of archaeological, geomorphological, pollen, and lake-level data show that northern Africa was considerably wetter than today during the early and mid-Holocene (ca. 11–5.5 ka). Experiments with an atmospheric general circulation model (AGCM) showed that both the broad-scale spatial patterns and the temporal evolution of these patterns could be explained to first order as a consequence of orbital (Milankovitch) forcing: gradual changes in the seasonal and latitudinal distribution of insolation through the Holocene caused a transition from a state with greater land–sea temperature contrast and an expanded and intensified African monsoon toward the aridity seen today (Figure 2).

COHMAP focused on using data–model comparisons for an improved understanding of the mechanisms of climate change, and this idea was subsequently taken up by many other modeling groups. However, it was rapidly realized that

simulations of the same time period made by different modeling groups and using different models differed from one another. It was difficult to diagnose the cause of these differences because the simulations did not always use the same external forcing or internal boundary conditions. The need to understand the causes of intermodel differences was the underlying motivation for the establishment of the Paleoclimate Modeling Intercomparison Project (PMIP) (Joussaume et al., 1999) in the early 1990s. The aim of this international project, which was sponsored by the World Climate Research Programme (WCRP) and the International Geosphere–Biosphere Programme (IGBP), was to analyze the causes of the differences in the responses of different models when run with identical forcing and boundary conditions. PMIP initially focused on two time periods: the Last Glacial Maximum (LGM) (ca. 21 ka) and the mid-Holocene (ca. 6 ka). These two intervals were chosen because they represent extremes of climate forcing (Table 1). As a result of changes in the configuration of Earth’s orbit, specifically in the phasing of the precession and obliquity cycles, Northern Hemisphere insolation was substantially greater than today during boreal summer (and on annual average) during the first part of the Holocene. At the LGM, the Earth’s orbital configuration was similar to that today but greenhouse gas concentrations were low, Northern Hemisphere ice sheets were greatly expanded and sea level was lower, the ocean surface was colder, and there was more sea ice in winter.

Through systematic model–model comparisons, PMIP was able to show that some features of the simulated climate changes were robust and independent of the model used, and to diagnose the causes of differences between the climates simulated by individual models. However, PMIP aimed to go further than this: to determine whether climate models are able to simulate past climates correctly through extensive evaluation using paleoclimate and paleoenvironmental data sets. The existence of adequate benchmarks for model evaluation is a ‘given’ for the evaluation of climate models under present-day conditions. However, the accurate simulation of modern climate is not a sufficient guarantee that a model will correctly simulate climatic conditions different from those today, such as those expected as a consequence of the continuing increase in greenhouse gas emissions during the twenty-first century. By evaluating the LGM and mid-Holocene simulations against standard paleoclimate benchmarks, PMIP was able to show how a comprehensive set of models responds to large changes in forcing. These evaluations were used in the third assessment report of the Intergovernmental Panel on Climate Change (IPCC) (Figure 3; McAvaney et al., 2001). PMIP is continuing the systematic benchmarking of the models used to predict future climate changes.

Requirements for Data Syntheses for Data–Model Comparison

Large-scale data syntheses are required to document the diagnostic spatial patterns (or ‘fingerprint’) of specific climate-change mechanisms (Anderson, 1995; Kohfeld and Harrison, 2000). Maps presenting a view of the world at some key time in the past on the basis of the interpretation of selected data in the

Table 1 Boundary conditions used for mid-Holocene (6 ka BP) and Last Glacial Maximum (21 ka BP) experiments by the Paleoclimate Modeling Intercomparison Project

Boundary conditions	Phase 1, AGCM			Phase 1, AGCM + mixed-layer ocean		Phase 2, OAGCM			Phase 2, OAVGCM

Figure 3 Examples of model evaluation using paleoclimate data for the mid-Holocene and Last Glacial Maximum (LGM) from the IPCC Third Assessment (McAvaney et al., 2001). The upper panel shows the latitudinal distribution of biomes across northern Africa today and at 6 ka BP (data derived from the BIOME 6000 dataset); the gray shaded area on the middle panel shows the increase in precipitation required at each latitude to cause a shift in vegetation from desert to grassland (steppe) and compares this to the changes in precipitation at each latitude simulated by the suite of AGCMs taking part in PMIP. The lower panel shows reconstructions of the magnitude of tropical cooling over land (data derived from the 21 ka TROPICS data set) and over the ocean (data derived from alkenone records) at the LGM and compares these reconstructions with the simulated change shown by multiple AGCMs and AGCMs coupled to a simple mixed-layer ocean model.

light of existing paradigms have long been part of the toolkit of Quaternary science. However, these maps are not suitable for systematic data–model comparisons or for model benchmarking. The creation of archival databases, such as the Global Pollen Database (GPD) (www.ncdc.noaa.gov), in the 1990s

represented a major step forward by ensuring access to large amounts of primary data and establishing full traceability for paleoreconstructions. Nevertheless, there is still a considerable amount of work required to produce data sets for model evaluation from these archive resources.

Data sets for model evaluation should have the following characteristics:

1. They should have a large enough spatial extent to distinguish regional patterns or ‘fingerprints.’ In practice, this means that the data set should be continental or ocean-basin-wide at a minimum, and preferably should be global in extent.
2. They should be transparent with respect to the primary data. Specifically, the data should be registered at individual sites and not spatially generalized in any way. This approach avoids the dual dangers of interpolating a signal on the basis of an inadequate conceptual model and of hiding the paucity of information for specific regions.
3. They should contain data that can be precisely located in time, and the time window should be limited in extent. In practice, the width of the time window that is considered acceptable depends on the magnitude and likely persistence of the climate signal being evaluated: given that the glacial state persisted for thousands of years and the difference between this state and the state today is large, it is generally considered acceptable to amalgamate data for a window of ± 1 ka around the glacial maximum for evaluation of glacial-type simulations. This approach would not be acceptable, however, if the aim of the model experiments was to evaluate the causes of climate oscillations within the glacial interval.
4. The data should be in a form that is directly comparable with model output. Initially, data sets for model comparison were focused on meteorological variables (e.g., July temperature, mean annual precipitation, and wind direction). The existence of offline models of components of the climate system, such as models of the marine and terrestrial biosphere or the dust cycle, means that a wide range of paleoenvironmental variables (e.g., vegetation type and dust-deposition rates) can now be used for model comparisons. The trend of using non-traditional variables for data–model comparison is likely to increase, as general circulation models evolve into full Earth-system models. However, the use of such variables places an additional constraint on the data syntheses, namely, that the controlling processes that give rise to particular kinds of records are well understood and made explicit in the data–model comparison process.
5. The data should be accompanied by adequate metadata (i.e., data describing the site, the record, and the age model) to allow users to select data for specific model comparisons.

Table 2 Large-scale and global data syntheses for model evaluation

<i>Data set</i>	<i>Variable</i>	<i>Region covered</i>	<i>Periods covered</i>	<i>Reference</i>	<i>Source</i>
GLSDB	Lake-level changes (runoff)	Global	Continuous from ca. 30 ka BP to present	Kohfeld and Harrison (2000)	Global dataset: BRIDGE website; Maps and data for selected time periods: PMIP2 website
BIOME 6000	Major vegetation types based on pollen and plant macrofossil data	Global	Modern, 6 and 21 ka BP	Prentice et al. (2000) and Pickett et al. (2004)	Maps and data for selected time periods: PMIP2 website
PAIN	Major vegetation types, based on pollen and plant macrofossil data	Northern high latitudes (N of 55° N)	Modern, 6 and 21 ka BP	Bigelow et al. (2003)	Maps and data for selected time periods: BRIDGE website
DIRTMAP	Mineral dust-deposition rates	Global, but predominately from ocean and ice-core sites	Past 150 ka, by marine isotope stages	Kohfeld and Harrison (2001)	Maps and data for selected time periods: BRIDGE website
SNOWLINE	Equilibrium line altitude of valley glaciers	Tropical (33° N–33° S)	Last Glacial Maximum, plus later glacial advance phases	Mark et al. (2005)	Maps and data for selected time periods: BRIDGE website
21ka TROPICS	Mean temperature of the coldest month, mean annual temperature	Tropical (33° N–33° S)	21 $\pm$ 1 ka BP	Farrera et al. (1999)	Global dataset: BRIDGE website; Maps and data: PMIP2 website
American monsoon	Multiproxy estimate of changes in effective moisture	North America and northern South America	Mid-Holocene (ca. 6 ka BP)	Harrison et al. (2003)	Maps and data: BRIDGE website
MARGO, LGM SSTs	Multiproxy estimates of mean annual SST	Global	21 $\pm$ 1 ka BP	Kucera et al. (2005)	Data sets: PANGAEA website
Holocene SSTs	Coccolith-based reconstructions of SST	Global	Holocene	Bollmann et al. (2002)	Data sets: NOAA NGD website
Marine productivity	Multiproxy estimates of marine productivity	Global	Marine isotope stages 5 through present	Kohfeld et al. (2005)	Maps and data: BRIDGE website

6. The data set should be adequately documented and publicly accessible in order to ensure full traceability of the data–model comparisons.

Requirements for Data–Model Comparisons

Early attempts to compare paleoenvironmental observations and model simulations were largely nonsystematic and subjective. This situation reflected the fact that the observations were reported on a site-by-site basis, and relatively few modelers had a command over the widely dispersed literature describing these records. However, the development of community-sponsored syntheses of different kinds of data means that it is now possible for comparisons to be made in a less *ad hoc* fashion. It is now widely accepted that data–model comparisons should fulfill certain basic requirements to be meaningful.

1. Data–model comparisons should be systematic and involve comparison with all of the available data from a region for a given time period. This avoids the situation of comparing model output with results from a few sites which might not be representative of the regional pattern of climate change.
2. Data–model comparisons should concern explicit model variables that can be matched to the controls on the paleo-observations. Thus, it is important to compare, for example, simulated July temperature with reconstructions based on proxies that respond explicitly to July temperature

rather than to some generalized requirement for warmth. In a similar way, comparisons of simulated changes in short-term variability in the El Niño/La Niña–Southern Oscillation (ENSO) signal cannot be evaluated by consideration of records that reflect changes in mean precipitation in ENSO-dominated regions.

3. They should be expressed in a way that makes it possible to evaluate matches/mismatches in an objective and quantitative way.
4. They should take into account the inherent variability of both the observed and simulated quantities being compared. In effect, this means taking into account the uncertainties in the paleoenvironmental reconstruction and the interannual variability in the simulated mean climate change.

Requirements for Model Benchmarking

The concept of ‘benchmarking’ is firmly entrenched in the procedure for evaluating performance in many areas of modeling, although the use of paleoclimatic and/or paleoenvironmental benchmarks for evaluating climate or Earth-system models is comparatively recent. The process of benchmarking simulations is based on the existence of a robust reconstruction of past climate or environmental changes, which can be used to measure the match to observations as models evolve. Thus, the requirements for benchmarks are somewhat different

Figure 4 The world in the mid-Holocene (6 ka). (a) Reconstructed vegetation patterns as shown by data from the BIOME 6000 data set (Prentice et al., 2000), and (b) changes in lake status, a measure of the regional change in runoff, as shown by data from the Global Lake Status Database (Kohfeld and Harrison, 2000).

Figure 5 The world at the LGM (21 ka, ca. 18 ka on the radiocarbon timescale). Reconstructed vegetation patterns as shown by data from the BIOME 6000 data set (Prentice et al., 2000) and changes in lake status, a measure of the regional change in runoff, as shown by data from the Global Lake Status Database (Kohfeld and Harrison, 2000). The location of the Northern Hemisphere ice sheets is based on the ICE 5G data set (Peltier, 2004).

from the requirements for data syntheses for data–model comparison. Broadly speaking, benchmarks must

1. reflect large-scale patterns corresponding to first-order changes in the climate system;
2. be robust with respect to multiple data sources and reconstruction techniques;
3. be adequately supported by data, and not be based on single records;
4. be expressed in a way that makes objective diagnosis possible.

The observed change in the African monsoon during the mid-Holocene has provided one such benchmark, which has been widely used for model evaluation (see below). PMIP has also developed a set of other regional benchmarks, which are now being used systematically for model evaluation.

Existing Paleoenvironmental Data sets for Data–Model Comparison

There have been a number of community-wide exercises to create paleoclimate or paleoenvironmental data sets for model evaluation (see Table 2). Many of these data sets are of regional scope. The most widely used global data sets are those provided by the Paleovegetation Mapping Project (BIOME 6000) (Prentice et al., 2000) and its daughter projects (e.g., Pan-Arctic Initiative (PAIN): Bigelow et al., 2003), the Global Lake Status Database (GLSDB) (Kohfeld and Harrison,

2000), the DIRTMAP database (Kohfeld and Harrison, 2001), the LGM Tropical Terrestrial Data Synthesis (LGM TROPICS) data set (Farrera et al., 1999), the Snowline Database (SNOWLINE) (Mark et al., 2005), and the Multiproxy approach for the Reconstruction of the Glacial Ocean (MARGO) project (Kucera et al., 2005). These various data sets present a picture of a world radically different from what it is today.

Paleoenvironmental data for the mid-Holocene indicate that the most pronounced changes in climate occurred in the region dominated by the Afro-Asian monsoon and in the high northern latitudes. Data from the GLSDB, for example, show that northern Africa between 15° and 30° N was occupied by large lakes and extensive wetlands (Figure 4(a)). The BIOME 6000 data set (Figure 4(b)) shows that the transition from grassland to desert, which marks the Sahel/Sahara boundary, was at least 5° further north than today. True desert vegetation seems to have been confined to a relatively small area in the northeastern part of the modern Sahara. Although the changes in Asia were more muted, lake, vegetation, and eolian data from this region all indicate an increase in the area affected by monsoon rainfall. In the high northern latitudes, vegetation reconstructions show that the tundra–taiga boundary was further north than it is today in Fennoscandia and central Siberia, although there was little change in other regions, and the tree-line was south of its present position in eastern Canada.

At the LGM, paleoenvironmental data show that regional climates were colder and generally drier than today (Figure 5). Forests were absent (or at least highly restricted) north of 55° N and the landscape was dominated by treeless vegetation, with

Figure 6 The tropics at the LGM (21 ka, ca. 18 ka on the radiocarbon timescale). The uppermost panel shows changes in dust deposition, as recorded in marine and ice-core records and by loess deposits on the continents, from the DIRTMAP database (Kohfeld and Harrison, 2001). The second panel shows changes in the equilibrium line altitude (Δ ELA) of tropical glaciers from the SNOWLINE database (Mark et al., 2005). The lower panels show reconstructed changes in mean annual sea-surface temperature from the MARGO project (Kucera et al., 2005) and reconstructed changes in mean temperature of the coldest month (MTCO) from the 21 ka TROPICS database (Farrera et al., 1999).

drier conditions giving rise to a significant expansion of graminoid and forb tundra, grassland, and xerophytic shrubland in northern and central Eurasia. Both lake and vegetation data indicate wetter conditions in the American Southwest, circum-Mediterranean region, and western China, most likely in response to the southward displacement of the westerlies caused

by the expanded northern ice sheets. The tropics were also colder and drier than today (Figure 6). Land-based temperature estimates from the LGM TROPICS data set indicate that the tropical lowlands were on average 2.5–3 °C cooler than today. These records show that the magnitude of the cooling differed regionally, with changes of only 1–2 °C in the

Figure 7 Changes (a) precipitation and (b) air temperature during the summer as a consequence of orbitally induced changes in incoming solar radiation (insolation) at 6 ka BP, based on a composite of the results of 17 AGCM simulations made within the first phase of the PMIP project.

Figure 8 Benchmarking model improvement in the simulation of the mid-Holocene expansion of the northern African monsoon as a consequence of including ocean and land-surface feedbacks. The first panel shows the results of simulations made with an atmosphere-only general circulation model (AGCM) during the first phase of PMIP; results from coupled ocean–atmosphere general circulation models (OAGCMs) and coupled ocean–atmosphere–vegetation models (OAVGCMs) run in the second phase of PMIP are shown in the middle and right-hand panels. This diagram shows that the incorporation of ocean- and land-surface feedbacks results in a more realistic amplification of the African monsoon, although there are considerable differences in the responses of individual models.

circum-Pacific lowlands and changes of 5–6 °C in Central and South America. At higher elevations, snowline data also indicate considerable regional differentiation with only muted changes in climate in the Himalayas, southern Andes, and East Africa, but much more pronounced lowering of snowline in the northern Andes, Central America, and Papua New Guinea. The MARGO data sets also show considerable spatial patterning in the magnitude of the cooling of the tropical oceans. Reconstructed sea-surface temperatures (SSTs) in the Caribbean, the South China Sea, and in the tropical Atlantic off the western coast of northern Africa were >5 °C lower than present, consistent with terrestrial reconstructions from the Caribbean and South China. The cooling in the equatorial belt was more muted: in the western Pacific Ocean, reconstructed changes in mean annual temperature are <2 °C while changes in the Indian Ocean and in the southern part of the tropical Atlantic are 2–4 °C. This patterning is also consistent with the terrestrial reconstructions from adjacent regions.

The Mid-Holocene African Monsoon: An Example of Data–Model Comparisons and Benchmarking

The expansion of the area influenced by the African monsoon is one of the most striking features of the mid-Holocene record (Figure 4) and has therefore figured prominently in data–model comparisons. It also provides an iconic example of the use of paleodata for benchmarking. The data show that at 6 ka most of the modern-day Sahara was covered by large lakes, extensive wetlands, and grassland. The precipitation required to generate the observed latitudinal grassland distribution has been estimated using both statistical methods and a simple vegetation–soil water-balance model. The observed shift from desert to grassland at 20° N would require an increase of 200–300 mm in mean annual precipitation (Joussaume et al., 1999). Independent calculations of the change in runoff required to maintain the observed lakes yield a similar estimate

of the change in mean annual precipitation. Thus, the mid-Holocene expansion of the African monsoon meets the suitability criteria for benchmarking in that the change in spatial pattern shown by the paleoenvironmental data reflects a major climate-change signal; it is based on a large number of individual site observations, it is robust with respect to two independent sources of evidence, and it can be expressed quantitatively in terms of a variable (i.e., mean annual precipitation) that is directly available from model simulations. Furthermore, as the paleoenvironmental records are drawn from global data sets (BIOME 6000 and the GLSDB, respectively) that conform to the requirements for model evaluation, this benchmark is well documented and fully traceable.

In the first phase of PMIP, comparisons with the observed expansion of the African monsoon were used to evaluate the response of a suite of 17 AGCMs to mid-Holocene changes in orbital forcing. All the models showed an increase and a northward shift in monsoon precipitation (Figure 7(a)) in response to the substantial heating of the northern continents (Figure 7(b)), thus increasing the land–sea temperature contrast. Initial data–model comparisons used mapped patterns of lake-level changes from the GLSDB to demonstrate that the simulated runoff ($P-E$) did not increase sufficiently in the northern Sahara. Subsequently, output from each of the climate models was used to drive an offline vegetation model to determine whether the simulated change in climate could reproduce the changes in vegetation patterns shown by data from the BIOME 6000 database. Finally, a systematic comparison of the model simulations against the monsoon benchmark was made. This comparison (Figure 8) showed that although all these models showed an increase and a northward shift in monsoon precipitation, they all underestimated the precipitation required to maintain grassland between 20° and 23° N by at least 150 mm. As a result of complex feedbacks associated with orbitally induced changes in SST (Kutzbach et al., 2001), coupled ocean–atmosphere general circulation models produce a more

Figure 9 Illustration of the iterative process of data–model comparisons, showing how the data–model comparison approach leads to a constant improvement in the quality and coverage of data syntheses and in Earth-system modeling capacity.

substantial enhancement of the African monsoon than atmosphere-only models. Nevertheless, only a few of the models produce sufficient rainfall to maintain grassland at 20° N, and all the models underestimate precipitation further north by at least 100 mm. Feedbacks associated with changes in land-surface characteristics as a result of changes in vegetation cover can also result in a substantial enhancement of the African monsoon. Preliminary benchmarking of the relatively few coupled ocean–atmosphere–vegetation simulations that have been run for the mid-Holocene confirm this enhancement.

Data–Model Comparisons: An Iterative Process

The confrontation of models and data is an iterative process (Figure 9). Apparent disagreements between model simulations and paleoenvironmental observations can arise from many causes including inadequate and/or unrepresentative data coverage, imperfect understanding of the climatic significance of the observations, incorrect specification of the climate forcing, or inadequacies in the climate model itself. Attempts to deal with the first two of these problems have led to the progressive improvement of the data sets for data–model comparisons, the development of objective techniques for reconstructing climate variables from the data, and the increasing use of models to simulate the response of environmental sensors to climate change. Each of these improvements gives rise to a new phase of data–model comparison. Persistent disagreement between model simulations and well-documented phenomena in the paleorecord has led to the discovery of new climatic mechanisms and to model improvement. A classic example once again involves the African monsoon. Once it was recognized that AGCMs systematically underestimate the quantitative increase in precipitation in the present-day Sahara in mid-Holocene times, scientists noted that the observed presence of large lakes and moisture-demanding vegetation in this region would have led to significant changes in land-surface albedo and surface roughness. Experiments made by prescribing altered mid-Holocene land-surface conditions within a climate model showed that land-surface feedbacks produce a substantial amplification of the orbitally driven changes in the African monsoon. The recognition that changes in land-surface conditions were potentially important feedbacks on the African monsoon has paved the way for the recent trend toward the inclusion of vegetation as an interactive component in climate models.

Introduction

The modeling of Quaternary climate provides a unique opportunity to test our understanding of the balance of processes that maintain climate and its variability. Despite all that can be gleaned from the decades of instrumental data that exist on recent climate history, these data do not reveal the significant interactions between the atmosphere, ocean, cryosphere, and biosphere as are suggested by Quaternary climate proxy records. One of the most pressing questions about climate today is how these components of the climate system will respond as a whole to the projected increases in atmospheric carbon dioxide concentrations. The observation and modeling of Quaternary climate has the potential to provide the necessary insights, yet there still is significant progress that is needed before this becomes a reality.

There exists a vast array of models of varying complexity that have been applied to the study of Quaternary climate. Computational limitations provide a strong constraint on the level of detail that may be considered, such as the temporal and spatial resolution or the number of interacting components included in any particular climate-modeling framework. The timescales relating to many of the leading questions about Quaternary climate change, such as glacial–interglacial cycles of ice sheets and the global carbon cycle, are too long to be considered by the same models that are being used to model future climate. To add to the confusion, many of these different modeling approaches do not give consistent answers.

This article discusses the strength and limitations of the many approaches to the modeling of Quaternary climates. A central theme is the struggle to identify and model the balance of processes that are relevant to any given question. A more detailed treatment of climate modeling and other topics relevant to modeling Quaternary climate are provided by McGuffie and Henderson-Sellers (2005), Washington and Parkinson (2005), Bradley (1999), Crowley and North (1996), and Trenberth (1992).

Assessing Model Applicability

Complexity

Climate models are becoming increasingly complex and are providing new opportunities to consider how and why changes in Quaternary climate come about based on first principles. However, understanding physical relationships within a complex model can be as challenging as interpreting the real world, and the computational costs may preclude doing all the experiments that one would wish, in order to extract those relationships. Much of the modeling of Quaternary climate that has taken place up to this point makes use of ‘reduced-order’ climate models. Reduced-order climate models are developed by exploiting some physical understanding of a

system, in order to reduce the number of spatial dimensions or temporal resolution considered, by parameterizing the missing physics or degrees of freedom in terms of quantities that are being resolved. Carefully conceived simple models representing relevant physics and balances are better suited to yielding insights and physical intuition than more complex models, which have the capacity to give realistic results but for the wrong reasons. Thus, the ability to explicitly control balances is one of the principle advantages of reduced-order models.

One of the simplest models that has been applied to the study of paleoclimate is an energy balance model (EBM). The radiative balance between incoming short-wave radiation F_{sw} and outgoing long wave radiation F_{lw} is one of the strongest constraints on climate prediction. A few simple equations can be used to capture the radiative and convective processes that maintain this balance to get an excellent approximation of, for example:

1. the size of the greenhouse effect from the doubling of atmospheric carbon dioxide levels;
2. the strength of the water vapor feedback assuming a constant relative humidity for a given change in saturation vapor pressure; and
3. an answer to why more complex models of future climate are extremely sensitive to uncertainties in the distribution of clouds.

Following a model presented by Goody (1995), the atmospheric lapse rate $\Gamma = -6.5 \text{ K km}^{-1}$ controls the linkage between the surface air temperature T_g , the altitude z_e , and temperature T_e of the layer within the mid-troposphere, called the emission level. This is emitting long wave radiation to space in balance with incoming solar radiation (Figure 1):

$$T_g = T_e + \Gamma z_e \quad [1]$$

The height of the emission level may be related to a unitless measure of the absorptivity of the atmosphere, known as its optical thickness τ ,

$$z_e = H \ln \frac{3\tau_1}{2} \quad [2]$$

where τ_1 is the optical thickness of the whole atmosphere and $H \approx 2 \text{ km}$ provides an approximate e-folding length scale of the decrease in long wave absorptive gas density (principally from water vapor) with height of the atmosphere. Given the fact that atmospheric CO_2 makes up about 12.5% of τ , with most of the remaining portion coming from water vapor for an Earth-like atmosphere where $\tau_1 = 8$, it can be estimated that the direct radiative effect of doubling CO_2 should produce $\sim 1.1^\circ \text{C}$ warming with an additional 4.1°C warming arising from changes in water vapor concentrations that would be predicted assuming that relative humidity remains constant. These results are quantitatively and physically consistent with the response of general circulation models (GCMs). Following

Figure 1 Conceptual greenhouse model of the relationship between surface air temperature T_g and the optical thickness of the atmosphere τ . Temperature is measured in units of degrees kelvin which is equivalent to degrees Celsius + 273.15. Adapted from Figure 5.9 of Goody R (1995) *Principles of Atmospheric Physics and Chemistry*. New York, NY: Oxford University Press, p. 324, with permission.

the example presented in Goody (1995), eqns [1] and [2] can be used along with the knowledge of the radiative properties of clouds, which act to either raise the altitude of the emission level z_e through increases in high clouds or decrease z_e by reflecting more short-wave radiation to space through increases in low clouds. Accordingly, the presence of observed concentrations of high clouds produces a net surface warming of 24 °C, whereas the presence of observed concentrations of low clouds produces a net surface cooling of 63 °C. Even this simple model of the greenhouse effect on climate, which does not take into account the complex physics of cloud formation, illustrates why clouds and water vapor are one of the primary sources of uncertainty in any model prediction of climate, whether relating to the past or the future.

Uncertainties

One of the more curious facts about model predictions of future climate is the surprising level of disagreement that exists among GCMs in their equilibrium surface air temperature sensitivity to a doubling of atmospheric CO_2 concentrations. This is despite their apparent success in reproducing observed surface air temperatures and surface air temperature trends over the last 100 years. The implication is that models are achieving agreement with the instrumental record of climate for different reasons. Differences in the treatment of clouds and radiation are likely to be important. Figure 2 shows observations and a range of model predictions for surface air temperature and percent total cloud cover, as obtained from the second Coupled Model Intercomparison Project (CMIP2). It is remarkable that the 12 models represented in the project achieved such close agreement in their predictions of surface air temperature, despite the extremely large range in predictions of total cloud amount. One of the reasons for the close agreement between the experimental predictions of surface air temperature is that nine of the experiments represented include

so-called ‘heat flux adjustments,’ which are extra sources or sinks of energy within the upper ocean that help models reproduce the observed sea-surface temperatures. Most modeling groups have moved away from the need to use heat flux adjustments, but as there has not been a parallel advancement in the understanding and elimination of sources of model uncertainty, it is assumed that the balances that maintain model climate are resulting from a different cancellation of errors.

Fortunately, there is broad agreement among climate models and climate proxies as to the large-scale qualitative response of the climate system to changes in the Earth’s orbital geometry, atmospheric $p\text{CO}_2$, and continental ice volume – for the particular late Quaternary time slices that have received most of the attention, including features of the last interglacial around 115 ka, Last Glacial Maximum (LGM) around 21 ka, and the mid-Holocene around 6 ka. However, this generalization does not apply in detail or with fields that are particularly sensitive to highly parameterized physics, such as clouds and precipitation.

One of the best ways to make an assessment of the uncertainty that exists for predicting changes in a given field of interest is to consider the range of predictions that exist among multiple climate models. At present, there are more than a few dozen model intercomparison projects that could be used in this way, with the results in Figure 2 being one example. This exercise is particularly effective for the kind of climate change experiments usually done for paleoclimate reconstructions, in which agreement among the models is less likely to be related to artifacts of the model tuning process and more likely to be related to physical processes or sets of processes that are well represented by the models. The series of volumes related to the IPCC assessments of global climate change contains excellent summaries of the current state of knowledge concerning global climate modeling, particularly with GCMs (IPCC, 2001).

Designing Models and Experiments

The climate models that exist for addressing questions of Quaternary climate change include compromises to meet the challenges of the range of processes of potential interest and the longer timescales involved. These compromises have the potential to interfere with reproducing the kind of balance of processes, and therefore sensitivities to external forcing, that exist in nature. A few examples are given here of choices that have been made to deal with the shortcomings of models, so that they may still be useful in addressing Quaternary climate science questions. An important point is that it has never been clear whether a given compromise is well justified, given the importance of the things known. Rather, the science of modeling Quaternary climate progresses as a sequence of tentative steps toward the objective of identifying and quantifying the dominant processes and assessing how these processes respond to a given forcing.

Heat Flux Adjustments

Major efforts in the modeling of Quaternary climate as a system of coupled component models have only recently begun.

Figure 2 DJF and JJA comparison between observations (solid and dashed lines), and the 1 (dark gray) and 2 (light gray) intermodel standard deviation among 12 coupled atmosphere–ocean general circulation climate models and their predictions of surface air temperature (in degrees kelvin, equal to degrees Celsius + 273.15; (a) and (b)) and percent total cloud cover ((c) and (d)) (AchutaRao et al., 2004).

Until recently (approximately year 2000), the coupling between a model atmosphere and model ocean required additional fluxes of heat energy at the ocean surface (the flux adjustments mentioned above), which are designed to keep coupled models from drifting into an unrealistic state. Most researchers considered it unwise to attempt flux-adjusted coupled atmosphere–ocean model experiments of paleoclimate, because the errors that were so delicately handled for present climate would contribute a significant amount of uncertainty to model predictions of past climates. Models still contain significant biases which, when integrated for a sufficiently long enough time, could undermine a model's usefulness. However, more care is now being given to ensure that a model's global and annual mean energy balances are satisfied. This helps considerably in reducing the chance that an error in model predictions would accumulate unchecked. While the potentially problematic issues of climatic drift are being successfully addressed, many models still may contain significant biases and compensating errors.

Boundary Conditions

Another common practice in experimental design is to specify the boundary conditions of a climate model that one does not have the capacity or interest in modeling. Examples of boundary conditions include sea-surface temperatures, sea-ice extent,

ocean-heat transports, wind stresses, meridional transports of water vapor, vegetation, carbon dioxide concentrations, continental ice sheets, and river runoff. Many of these boundary conditions come from climate proxy data and the effort to provide global coverage for quantities like surface vegetation or the three-dimensional distribution of continental ice sheets is challenging and fraught with uncertainty. The idea is that all of the active components of the climate model would respond in the same way to the fixed boundary conditions as they would if the boundary conditions were predicted by a model. The extent to which this is true is not obvious.

One particular example that has received considerable attention is the reconstruction of sea-surface temperatures and sea-ice extent during the LGM (~21 ka BP), obtained through the CLIMAP project (Climate/Long-Range Investigation, Mapping and Prediction; CLIMAP Project Members, 1976) and updated by MARGO (Multiproxy Approach for the Reconstruction of the Glacial Ocean surface; Kucera et al., 2005). The purpose of modeling experiments that make use of these data as boundary conditions is to test the understanding and interpretation of land-based climate proxy records in terms of atmospheric processes. The lack of agreement between model predictions based on CLIMAP boundary conditions and many climate proxy records in the tropics raised questions about the accuracy of the reconstructed sea-surface temperatures, which

indicate little change from present across vast portions of the subtropics. From a modeling and experimental design point of view, the discrepancy raises a central point in the discussion about the balances that are being represented in models. Specifying sea-surface temperatures influences the sources or sinks of energy that are available to the atmosphere. If a large part of the ocean is kept unnaturally warm with respect to energy fluxes being provided by the atmosphere, the imbalance will shape a portion of the total solution that could affect model sensitivities important to particular scientific questions. Modeling groups differ widely in their willingness to design an experiment with this potential source of uncertainty.

An alternate experimental design that has helped in this regard is an atmospheric GCM that is coupled to a slab ocean of specified thickness. The slab ocean provides a representation of the thermal memory of the upper ocean but does not explicitly consider how upper-ocean temperatures may be affected by changes in ocean circulation or mixing. Ocean-heat transports are represented through heat-flux adjustments that only vary with the seasonal cycle. They are usually designed to provide the exact amount of heat energy required to support the observed climatological sea-surface temperature distributions. Maps of these flux adjustments show largely what would be expected from the effects of ocean currents on the transport of heat from the tropics and its release along the western boundary currents and the high northern latitudes where deep-water formation is taking place (Figure 3). These maps also include fluxes that compensate for biases that may exist in the model atmosphere. The predictions of LGM climate using an atmospheric GCM coupled to a slab-ocean model show a 1–2 °C cooling in the tropics and compare favorably with the 2–3 °C average cooling in experiments that include a dynamic model of the ocean (Figure 4). Currently, there is considerable uncertainty in atmosphere–ocean GCMs as to the rate of deep-water formation in the polar regions. In this case, it is helpful

to know how much of the LGM climate may be reproduced if ocean currents are unchanged. The experimental design of an atmosphere GCM coupled with a slab ocean can provide a helpful complement to the experiments that estimate the aspects of modeled climate change that exist because of atmospheric rather than oceanic processes.

Equilibration

Another source of uncertainty that has arisen with the advent of coupled atmosphere–ocean GCM experiments is the question of model equilibration. Predictions of paleo-ENSO (El Niño/Southern Oscillation) may be particularly sensitive to equilibration, as ENSO dynamics are very sensitive to processes that affect the structure of the thermocline. Stouffer (2004) found that the tropical Pacific thermocline required 200–300 years to attain 70% of its final equilibrium solution when forced by a cooling perturbation (Figure 5). The deep ocean requires the longest equilibration timescales of approximately 2000 years.

Considering many large-scale, and at times rapid, changes in climate throughout the Quaternary, it may have been unusual for the ocean to have ever been in equilibrium with changes in external forcing. This may add considerably to the uncertainties of modeling Quaternary climate. More needs to be done to quantify the potential problems this may create for model-data comparisons.

Examples

Stability of the meridional overturning circulation

The question of the ocean's response to high-latitude freshening is prominent in Quaternary climate-modeling studies because of the likelihood of sudden changes in continental ice sheet mass balance, particularly in connection with episodes of

Figure 3 Example of annual mean heat flux adjustments applied to an atmospheric general circulation model (GCM) coupled to a 50-m slab ocean (Jackson and Broccoli, 2003).

Figure 4 Dynamic versus slab-ocean versions of the Hadley Center climate model predictions of annual mean surface air temperature of Last Glacial Maximum climate change from present: (a) dynamic ocean experiment using HadCM3, (b) slab-ocean experiment using HadSM3, (c) HadCM3–HadSM3. Crown Copyright 2006.

abrupt climate change. There exists a complex interplay as to the relative importance of thermal versus salinity forcing of the Atlantic Ocean's meridional overturning circulation and the role of the different parameterizations of horizontal and vertical mixing in the maintenance and stability of this circulation. A recent model intercomparison project considered the similarities and differences across a range of model classes,

including models of intermediate complexity (reduced-order models) as well as atmosphere–ocean GCMs. Of interest was the similar amplitude of the weakening that was predicted to occur across the different model designs, as well as the expression of these changes on surface climate across the globe for both weak and strong forcing experiments (Figure 6). One of the fundamental differences between the experiments

Figure 5 Time in years to reach 70% of the equilibrated response of the Pacific and Atlantic Ocean basins for a doubling ((a) and (b)) and halving ((c) and (d)) of atmospheric $p\text{CO}_2$ (Stouffer, 2004).

was the potential for the reduced-order ocean models to become locked in a state with a weak overturning circulation. It would appear that the mixing of ocean properties in ocean GCMs is a key part of their eventual recovery after forcing perturbations have ceased. This has potential implications for the interpretation of abrupt climate change, which conceptually has depended on the multiple stable equilibria observed in reduced-order models, in order to explain abrupt climate changes during the last-glacial cycle.

Glacial–interglacial changes in the carbon cycle

A range of model complexities have been formulated to consider hypotheses concerning glacial–interglacial changes in atmospheric CO_2 concentrations. These models consider processes that potentially affect the different pools of carbon that exist in the ocean and their preservation in ocean sediments. Many of these pools of carbon are either chemically or physically inaccessible for gas exchange with the atmosphere.

The relative sizes and exchange of carbon between these pools are controlled by numerous processes including ocean biology, availability of nutrients through ocean currents and supply through the atmosphere to the ocean surface, ocean temperatures, mixing between different water masses, ocean pH and alkalinity, and burial in sediments. The record of the preservation of calcium carbonate and opal in ocean sediments and proxies sensitive to ocean geochemistry and currents provides some constraints on the different hypotheses that have been proposed. However, there exists a curious dichotomy in the results of modeling studies that, depending on the modeling approach taken, suggests that the hypotheses that have been considered are either all insufficient (Archer et al., 2000a) or all sufficient (Legrand and Alverson, 2001) to explain the changes in the carbon cycle from LGM to present.

One of the focal points in the discussion of why these differences exist concerns the role of the low versus high

Figure 6 Surface air temperature response within an ensemble of (a) atmosphere–ocean GCMs and (b) models of intermediate complexity after 100 years of applying a 1 Sv ($10^6 \text{ m}^3 \text{ s}^{-1}$) (equivalent to raising sea level by 9 m) forcing to the North Atlantic (Stouffer et al., 2006).

latitudes in controlling the ocean's equilibration with the atmosphere (Archer et al., 2000b; Toggweiler et al., 2003). The warm water temperatures in the equatorial regions make carbon much less soluble in these waters than in the cooler polar waters. Because the pool of warmer tropical waters exchanges gases less effectively with the deep ocean than the surface waters of the higher latitudes, box models show that the higher latitudes would be much more important in these exchanges. The larger amount of vertical mixing in ocean GCMs appears to diminish the strength of this effect. However, because there still exists a significant amount of uncertainty concerning both the processes governing and the overall amplitude of vertical mixing in the world's oceans, the correct balance is not clear. Also being debated is the rate of horizontal mixing in the ocean that could be important for regulating the area of the ocean surface that is equilibrating with the atmosphere, and its effective exchange with the deep-ocean reservoir of carbon (Archer et al., 2003; Toggweiler et al., 2003). Box models assume that all water within a given box is well mixed, and so, these models tend to be overly efficient in their gas equilibration with the atmosphere, relative to how these processes are controlled in an ocean GCM. Therefore, box models show the plausibility of a number of hypotheses. The details of these hypotheses could potentially be worked out within ocean GCMs, but more

work is needed to establish whether ocean GCMs are modeling natural processes accurately.

Conclusions

The primary scientific opportunity of modeling Quaternary climate is to understand how the climate system operates as a whole. The precise balance of processes that maintain a given climate state is not readily apparent in instrumental data, nor is it obvious in comprehensive models of climate. The choices that are made to represent the climate system simply potentially affect how a model treats these balances, leading to misleading sensitivities. As was illustrated by the efforts to model glacial–interglacial changes of the carbon cycle, simplified models often are more sensitive than atmosphere–ocean GCMs. While there may be fewer explicit assumptions with GCMs, it is harder to know how to control the balance of processes that are being played out within them. Comparing two climate change experiments among several models could potentially provide some guidance as to which model predictions are more robust than others. Finally, it should not matter whether a model is made up of a few boxes with parameterized physics or millions of boxes with physical processes being resolved, if one is correctly capturing the relevant balances.

Getting to know what those balances should be is what makes modeling Quaternary climate interesting.

This article is reproduced from the previous edition, volume 3, pp. 1916–1927, © 2007, Elsevier B.V.

Introduction

The last interglacial maximum (LIG; ca. 125 ka BP), also referred to as Marine Isotopic Stage (MIS) 5e or Eemian because of the warm biostratigraphic assemblages found for this time period in the Eem Valley (the Netherlands), is of interest for both modelers and geologists. In addition to being considered the warmest time period of the last 200 ka, its end represents the best documented transition from an interglacial to a glacial state (Kukla et al., 2002) and is relevant for our understanding of future anthropogenic global warming: although the forcing factors are very different, an adequate simulation of past warm periods enhances our confidence in climate models and thus in future climate projections.

Evidence for warmth during the LIG relies mainly on terrestrial and marine records from mid- and high northern latitudes (e.g., Aalsbersberg and Litt, 1998; Klotz et al., 2003; LIGA Members, 1991 and references therein; Zagwijn, 1996; see Figure 1). In agreement with isotopically light $\delta^{18}\text{O}$ values from the deep-sea record (e.g., CLIMAP, 1984 and references therein), global sea level may have been up to 6–7 m higher than the present level (Crowley and North, 1991 and references therein), implying a significant reduction in global ice volume, corresponding to the total of the Greenland or the West Antarctic ice sheets. Vostok ice-core data indicate carbon dioxide (CO_2) and methane (CH_4) levels comparable to pre-industrial ones and local temperatures about 2 °C higher than present (e.g., Petit et al., 1999). In contrast, sea-surface temperature (SST) reconstructions (CLIMAP, 1984) suggest that values were not significantly higher than that today (Figure 2).

Climate simulations of the LIG have been carried out with atmosphere-only general circulation models (AGCMs; e.g., De Noblet et al., 1996; Khodri et al., 2003; Kutzbach et al., 1991; Prell and Kutzbach, 1987; Royer et al., 1984), AGCMs coupled with static mixed-layer ocean models (e.g., Hall et al., 2005; Harrison et al., 1995), coupled atmosphere–ocean general circulation models (AOGCMs; e.g., Felis et al., 2005; Groll et al., 2005; Kaspar and Cubasch, 2005; Kaspar et al., 2005; Montoya et al., 1998, 2000), Earth system models of intermediate complexity (EMICs; e.g., Kubatzki et al., 2000), and energy balance models (EBMs; e.g., Crowley and Kim, 1994). Initially, the focus was mainly on the direct thermodynamic response to the insolation changes, such as that at high latitudes and in the monsoons (e.g., Harrison et al., 1995; Kutzbach et al., 1991; Prell and Kutzbach, 1987). More recently, modeling studies have focused on changes in dynamics forced by changes in insolation (Felis et al., 2005; Groll et al., 2005; Hall et al., 2005). EMICs have also been used to analyze the role of specific climatic components or forcing factors and to investigate the reasons for discrepancies between EMIC and AOGCM results (Kubatzki et al., 2000).

In this article, the latter studies are reviewed, focusing on equilibrium climate simulations of the LIG. After describing

the typical model setup, the seasonal and annual mean responses are analyzed, focusing on the changes in the surface-air temperature (SAT), the southwestern monsoons, atmospheric dynamics, and ocean circulation, and the role of vegetation feedbacks. Finally, the main conclusions are summarized, aiming at establishing robust model responses, the main disagreements among models, and the remaining open questions.

Boundary Conditions

Climate simulations of the LIG based on GCMs, which are computationally expensive, have mainly consisted in so-called equilibrium or time-slice simulations in which the relevant boundary conditions or external forcing factors are changed and the model is integrated until the simulated climate is in equilibrium with the specified forcing. Owing to the long timescales of some of its components, climate is really seldom in equilibrium with its boundary conditions, but in sufficiently long and relatively stable time periods, and as a first step, this constitutes a reasonable approach.

Since the establishment of Milankovitch's astronomical theory of ice-ages, variations in the insolation received by the Earth at the top of the atmosphere following variations in the Earth's orbital parameters are recognized as the key factors driving climate on orbital timescales (about 10^4 – 10^6 years), that is, glacial–interglacial cycles. Time-slice experiments are thus carried out by prescribing the Earth's orbital parameters at a given time period (Berger, 1978), which determines the insolation at the top of the atmosphere at that time. Table 1 shows the orbital parameters for 125 ka BP, suitable for a time-slice climate simulation of the LIG, together with those for the present. At 125 ka BP, the eccentricity of the Earth's orbit was greater, obliquity was slightly greater, and perihelion took place in northern summer instead of in northern winter as it does today (Figure 3). As a consequence, northern summer insolation was greater at 125 ka BP than it is today at all latitudes, with a peak value of 60 W m^{-2} at high northern latitudes (Figure 4). On average, insolation increased by 50 W m^{-2} (12%). Northern winter insolation decreased at all latitudes with an average value of 26 W m^{-2} (11%). At high latitudes, the decreasing effect of the timing of perihelion on insolation was partly compensated by the greater obliquity. Hence, maximum northern winter insolation decreases took place in the southern subtropics. To summarize, the seasonal cycle of insolation was amplified in the Northern Hemisphere and attenuated in the Southern Hemisphere. Mean annual insolation increased at high latitudes, where enhanced summer insolation is not offset in winter, and decreased at low latitudes, but the departure was below 2 W m^{-2} at all latitudes (not shown), and its globally averaged change was negligible (0.23 W m^{-2}).

Variations in greenhouse gases (GHGs) are also taken into account (Table 1). The CO_2 concentration is prescribed to be

Figure 1 Temperature conditions at selected sites during the last interglacial (LIG) maximum as compared to modern values. Reprinted from LIGA Members (1991) Report of 1st discussion group: The last interglacial in high latitudes of the Northern Hemisphere: Terrestrial and marine evidence. *Quaternary International* 10–12: 9–28, © 1991, with permission from Elsevier.

about 270 ppmv, consistent with mean levels for the LIG estimated from ice-core measurements. This is similar to preindustrial levels (Petit et al., 1999). Although in the past control runs have been carried out with higher CO₂ levels (e.g., Khodri et al., 2003; Montoya et al., 2000), it is now recognized that the present climate is not in equilibrium with such high CO₂ levels, and that it is more reasonable to use a preindustrial level. In some simulations, other GHGs such as CH₄ and nitrous oxide (N₂O) have additionally been taken into account (Groll et al., 2005; Kaspar and Cubasch, 2005; Kaspar et al., 2005). Simpler models such as EMICs include interactive biosphere components (Kubatzki et al., 2000). Finally, since the estimated 6-m sea-level rise at the LIG relative to the present leads to negligible changes in the model land–sea mask, the latter is kept as in the control run.

Seasonal Responses

Owing to the wealth of proxy data for the LIG showing evidence for warmth at mid–high northern latitudes (e.g., LIGA Members, 1991) and for stronger southwestern monsoons in South Asia and Africa (e.g., Prell and Kutzbach, 1987), from the modeling perspective, attention has focused mainly on the latter regions. However, recently the role of changes in dynamics, especially in northern winter, has been highlighted.

Northern Summer Response: Direct Response to Insolation

The June–August (JJA) SAT responses simulated by all models, from EBMs to coupled AOGCMs (e.g., Crowley and Kim, 1994; De Noblet et al., 1996; Felis et al., 2005; Groll et al., 2005; Harrison et al., 1995; Kaspar and Cubasch, 2005; Kaspar et al., 2005; Kubatzki et al., 2000; Montoya et al., 2000; Prell and Kutzbach, 1987), agree well with one another and with the evidence for enhanced warming at the LIG from paleodata (e.g., Aalsbersberg and Litt, 1998; Klotz et al., 2003; LIGA Members, 1991; Zagwijn, 1996). As an example, Figure 5 shows the 2-m-temperature departures with respect to the control run of one of the most recent climate simulations of the LIG with a state-of-the-art coupled AOGCM (Groll et al., 2005; Kaspar and Cubasch, 2005; Kaspar et al., 2005). The JJA anomalies reflect the direct thermodynamic response to the insolation changes: as a consequence of the increase of insolation (Figure 4), models simulate overall enhanced warming over land. The largest departures are found in the northern continents, where the increase in both radiative forcing and the land-mass distribution, with low heat capacity compared to that of the ocean, are greatest. Owing to the large thermal inertia of the ocean, the SAT response is generally stronger in atmosphere-only models, some of which show maximum departures above 10 °C over the Eurasian continent (Khodri et al., 2003; Royer et al., 1984), compared to coupled atmosphere–ocean models,

in which the maximum SAT increases are $\sim 4\text{--}6^\circ\text{C}$ (Felis et al., 2005; Kubatzki et al., 2000; Montoya et al., 2000). For the same reason, the SAT response over the ocean is generally below 1°C (e.g., Groll et al., 2005; Harrison et al., 1995; Kaspar and Cubasch, 2005; Kubatzki et al., 2000; Montoya et al., 2000; see also Figure 5). The exceptions are the high northern latitudes, where insolation anomalies are largest (Figure 4) and SAT departures are amplified through the positive sea-ice albedo–SST feedback, that is, the sea-ice reduction following the increased JJA warming leads to enhanced absorption of surface solar radiation which further enhances the warming. This effect is not limited to JJA, but takes place all-year round (see below).

A common feature of many models including AGCMs (e.g., De Noblet et al., 1995; Felis et al., 2005; Groll et al., 2005; Khodri et al., 2003; Montoya et al., 2001; Royer et al., 1984) is a belt of reduced SATs over Central Africa and South Asia, related to the strengthened monsoons and enhanced cloud cover (not shown) in these areas. This is consistent with paleo-reconstructions of monsoon-related climatic indices suggesting

**Figure 4** Monthly mean insolation at the top of the atmosphere in watts per square meter (W m^{-2}) as a function of latitude for 126 ka BP minus present with 126 ka BP based on angular months. intensified monsoons during interglacial periods (e.g., Prell and Kutzbach, 1987). This result can be understood through the simulated response of the models, summarized in Figure 6: the JJA sea level pressure (SLP) change reflects the direct thermodynamic response to the JJA continental warming, decreasing over the warmer landmasses, especially over Eurasia, North Africa, and North America, and increasing, or decreasing less, over the cooler surrounding oceans (Groll et al., 2005; Khodri et al., 2003; Kubatzki et al., 2000; Montoya et al., 2000). As a consequence, the land–ocean SLP gradient is enhanced. In the Tropics, this leads to an intensification and northward migration of the on-shore low-level convergent flow, and thus of moisture transport further inland into equatorial Africa and South Asia, and a strengthening of the tropical easterly jet at high levels. This response reflects an intensification of the African and southwest Asian monsoons (De Noblet et al., 1995; Groll et al., 2005; Kubatzki et al., 2000; Montoya et al., 2000; Prell and Kutzbach, 1987). AGCMs suggest that the total precipitation is not affected significantly (De Noblet et al., 1995). However, EMICs suggest that when an interactive biosphere component is included, precipitation departures, both in JJA and in the annual mean, virtually double because of the existence of vegetation–precipitation feedbacks: the increase in precipitation at the LIG leads to an expansion of vegetation; subsequent changes in the radiation balance lead to a surplus in available energy used for evaporation. The increase in atmospheric total energy (sensible plus latent heat) results in enhanced convection and, together with changes in

Figure 5 Departure in 2-m-temperature (125 ka BP minus control) in degrees Celsius ($^{\circ}\text{C}$) for (a) JJA, (b) DJF, and (c) annual mean, as simulated by the ECHO-G AGCM. Courtesy of F. Kaspar.

the moisture advection, in additional precipitation increase (Kubatzki et al., 2000 and references therein). As a consequence, 97% of North Africa is covered by vegetation, mainly grasses (Figure 7).

Northern Winter Response: The Role of Atmospheric Dynamics

Consistent with the decrease in insolation at almost all latitudes in December–February (DJF), models show considerable cooling over the continents (Figure 5). Although the maximum insolation decreases take place in the southern subtropics (Figure 2), maximum cooling takes place in the northern subtropical continents because of the larger fraction of surface covered by the ocean in the southern subtropics. As a consequence of the enhanced JJA insolation at high northern latitudes and the positive sea-ice albedo–SST feedback, in JJA, the heat storage by the ocean increases. This results in a delay in the onset of Arctic sea-ice growth in autumn, accelerated melting in

spring, and an all-year round warming (Figure 5, DJF) and sea-ice thickness and extent decrease (not shown). In models including oceanic components, warming up to 4°C , centered in the Arctic, takes place in DJF (e.g., Groll et al., 2005; Kubatzki et al., 2000; Montoya et al., 2000; see also Figure 5). In these aspects that reflect the direct thermodynamic response to insolation changes, the simpler models, such as EMICs (e.g., Kubatzki et al., 2000), are in good agreement with more complex models (e.g., Felis et al., 2005; Groll et al., 2005; Montoya et al., 2000).

However, models including AGCMs, even with SSTs prescribed to their present-day values, simulate considerable warming in DJF at mid-northern latitudes of Eurasia and North America (e.g., Groll et al., 2005; Harrison et al., 1991; Kaspar and Cubasch, 2005; Kaspar et al., 2005; Montoya et al., 1998). The warming pattern (Figure 5) agrees well with January SAT reconstructions based on pollen and plant macrofossil assemblages (Kaspar et al., 2005). Harrison et al. (1991) already showed such a warming as a consequence of stronger westerly winds, together with a northward shift and strengthening of the wintertime Atlantic jet, bringing warm and moist air into central and northeastern Europe. Kaspar and Cubasch (2005) have shown that the latter changes are a consequence of the SLP response over the North Atlantic, which is a dipole showing enhanced SLP over the subtropics and reduced SLP at high latitudes, comparable to a high-index state of the Arctic Oscillation (AO), which is the main mode of DJF northern extratropical climate variability.

An intensification of the AO index during the LIG was first suggested by Felis et al. (2005), who analyzed their AOGCM LIG climate simulation in comparison with coral records of the Red Sea, which indicated increased temperature seasonality during the LIG compared to the present. The AOGCM simulations suggest that this result is a consequence of the higher AO index leading to colder winters in the Middle East during the LIG compared to the present. This result is supported by the close correlation found between the present-day SST anomalies of the Red Sea and the AO index in the observations and simulations, for both the present day and the LIG. Furthermore, in an ensemble of transient simulations for the LIG with this model, the simulated AO index throughout most of the period is significantly higher than that for the modern climate.

A similar conclusion was reached by Hall et al. (2005), who studied the response of their AGCM coupled to a mixed-layer ocean model to insolation variations throughout the last 165 ka. To this end, they decomposed the model's circulation response into a linear response to obliquity and precession (orbital response) and a residual, mainly due to internal variability. In JJA, the orbital response is a local thermodynamic one to insolation changes, as described above. However, in DJF, the orbital response includes a dynamic response which is very similar to the AO (Figure 8). This result is consistent with models showing a northward shift of the Atlantic jet (e.g., Harrison et al., 1991; Kaspar and Cubasch, 2005; Kaspar et al., 2005; Montoya et al., 2000). Furthermore, European SATs are shown to be out of phase with DJF insolation changes but almost perfectly in phase with the orbital AO index, both reaching their maximum values at ca. 120 ka BP, when as a consequence of enhanced advection of warm, moist air into Europe, the model generates a $1\text{--}2^{\circ}\text{C}$ warm SAT anomaly over

Figure 6 Departures (LIG minus control) of surface temperature (T), SLP, winds (arrows), and precipitation (P) for the Indian Ocean sector. Sea ice is indicated by vertical stripes. Figure 7 Departure (LIG minus present) in forest fraction (top) and desert fraction (bottom) simulated by the CLIMBER-2 EMIC in the model version including interactive atmospheric, oceanic, and biosphere components.

Europe (Figure 5). This result is consistent with temperature reconstructions indicating warmer than present LIG temperatures (Aalsbersberg and Litt, 1998; Klotz et al., 2003; LIGA Members, 1991; Zagwijn, 1996) and provides an explanation of the warm winter anomaly.

Annual Mean SAT Response and Globally Averaged Temperatures

Owing to the widespread evidence for warmth during the LIG, it has often been discussed whether globally averaged temperatures were significantly higher than the present temperature (e.g., Kubatzki et al., 2000; Montoya et al., 1998). Proxy data indeed indicate enhanced warming at high northern latitudes (e.g., LIGA Members, 1991), but SSTs were not significantly higher than the present value (CLIMAP Project Members, 1984). Coupled atmosphere–ocean climate models generally do not suggest significantly higher global temperatures either. The reason is that despite the large warming simulated in northern summer, most models show significant cooling in winter (e.g., Groll et al., 2005; Kubatzki et al., 2000; Montoya et al., 2000), with the net result that, except certain specific regions such as the Arctic and some regions in Eurasia, the mean annual SAT and SST changes are below 1 °C almost everywhere (e.g., Groll et al., 2005; Montoya et al., 2000; see also Figure 5). Montoya et al. (1998) compared the SST response simulated by their AOGCM with the CLIMAP Project Members (1984) SST reconstruction on a point-by-point basis (Figure 9). This high level of agreement suggests that the model results are consistent with the CLIMAP Project Members (1984) SST reconstruction for the LIG and supports the inference of similar or slightly higher mean annual and global temperatures.

Vegetation Feedbacks

However, one mechanism by which warming at the LIG might have been amplified all-year round, especially at mid- and high northern latitudes, is through vegetation feedbacks, as shown

Figure 8 Top: First empirical orthogonal function (EOF) for orbital SLP variability north of 26°N , for JJA (left) and DJF (right). The patterns account for 96% and 80% of the total variance. Bottom: time series of 30-year-mean DJF SAT anomaly ($^{\circ}\text{C}$) averaged over the model's European continent (raw SAT, light gray), orbital DJF SAT ($^{\circ}\text{C}$) averaged over the model's European continent (solid), primary mode of orbital SLP variability (dashed), and DJF incoming insolation due to Milankovitch forcing averaged over the same latitudes, normalized by its standard deviation (dashed-dotted). Reprinted from Hall A, Clement A, Thompson DWJ, Broccoli A, and Jackson C (2003) The importance of atmospheric dynamics in the Northern Hemisphere wintertime climate response to changes in the Earth's orbit. *Journal of Climate* 18: 1315–1325, © 2003, with permission from the American Meteorological Society.

by Kubatzki et al. (2000) by including in their EMIC an interactive terrestrial vegetation module. This amplification is caused by the synergism between the sea-ice albedo–SST feedback and the vegetation–snow albedo feedback: because of warmer summers and long growing seasons during the LIG, boreal forests expanded northward. Since the snow coverage of high vegetation (trees) is less efficient than that for low

vegetation (grass or polar desert), the surface albedo thus decreases. Together with the earlier snow melting, this results in additional warming. As a result, the sea-ice area is further reduced and the area covered by boreal forests increases considerably (as an example, it doubles at 65°N), at the expense of tundra and polar desert (Figure 7) Maximum SAT differences over Eurasia increase up to 7°C in JJA, while in DJF, the Arctic

Figure 9 CLIMAP Project Members minus model-simulated annual mean SST anomalies (estimated as the summer and winter average SSTs) in degrees Celsius at CLIMAP core locations (blue indicates that the CLIMAP anomaly is colder than that predicted by the model, red indicates that it is warmer, and green indicates that there is no significant different at $1 - \sigma$ level). Reproduced from Montoya M, Crowley TJ, and von Storch H (1998) Temperatures at the last interglacial simulated by a coupled ocean-atmosphere model. *Paleoceanography* 13: 170–177, © 1998 American Geophysical Union, with permission.

warming reaches 8°C (Figure 10). In the annual mean, the Arctic Ocean and the northern continents are about 4 and 1°C warmer, respectively (not shown). Thus, the change in globally averaged temperature increases from 0.4 to 1.2°C when interactive vegetation is taken into account (see above). Because the effect is higher over land as well as at high latitudes, the good agreement with CLIMAP Project Members (1984) SSTs is not compromised. Thus, vegetation feedbacks might result in globally warmer conditions which cannot otherwise be accounted for. Such changes in vegetation are indeed consistent with vegetation reconstructions, indicating a northward expansion of boreal forests (e.g., LIGA Members, 1991).

Ocean Circulation Changes

Recent density reconstructions for the LIG indicate the presence of a fresh surface layer in the Labrador Sea which inhibited winter convection and, thus, Labrador Sea Water (LSW) formation (Hillaire-Marcel et al., 2001). This state lasted throughout the whole glacial cycle, and LSW formation resumed only during the Holocene, at about 7 ka BP. However, Denmark Strait Overflow Water (DSOW) production rates were still high. This means that, instead of the current LSW/North Atlantic deepwater (NADW) stratification, below a certain depth a single water mass occupied the North Atlantic basin.

Cottet-Puinel et al. (2005) have used the UVic coupled climate model, an EBM coupled to an OGCM, to analyze

LSW formation at the LIG. For the preindustrial climate, their model shows deepwater formation in the Labrador Sea as well as in the Irminger Sea instead of the GIN Seas, which is a common feature of coarse resolution models. However, for the LIG, deepwater formation occurs only in the Irminger Sea, in agreement with Hillaire-Marcel et al. (2001). As a result, the amplitude of the Atlantic meridional overturning circulation (AMOC), of 21 Sv ($1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$) in the control run, is reduced by about 6 Sv and is shallower, and Antarctic bottom water (AABW) penetrates slightly farther north, consistent with reconstructions of Duplessy et al. (1988). The model reproduces the fresh lid in the Labrador Sea found in the reconstructions. Hillaire-Marcel et al. (2001) argue that this is a consequence of enhanced export of fresh water out of the Arctic, possibly associated with an intensification of the hydrological cycle in the warmer LIG climate. However, Cottet-Puinel et al. (2004) discuss that in their model it is rather the consequence of enhanced sea-ice coverage due to the insolation decrease. As a consequence of the LSW formation halt, the model shows a decrease in SAT of up to 1.5°C centered over the North Atlantic, which is not consistent with the year-round warming at the LIG inferred from paleodata. Still, this could be due to excessive diffusion due to its relatively simple atmospheric component.

Other than that, modeling studies have not focused much on differences in the ocean circulation at the LIG relative to the present. The simulated changes are generally of small amplitude. Montoya et al. (2000) found a slight intensification of

Figure 10 Departure in SAT (125 ka BP minus control) in kelvin for JJA (top) and DJF (bottom), as simulated by the CLIMBER-2 EMIC in the model version including interactive atmospheric, oceanic, and biosphere components.

the meridional overturning circulation in their AOGCM, in both the Atlantic and the Pacific Oceans, linked to enhanced evaporation at high northern latitudes. In contrast to this, the model simulation by Kubatzki et al. (2000) obtained a decrease, due to enhanced warming during the LIG. Crowley and Kim (1994) showed enhanced inflow of AABW into the Pacific, consistent with Montoya et al. (2000). Groll et al. (2005) indicate only minor changes of NADW formation rates during the LIG. These results are consistent with $\delta^{13}\text{C}$ data suggesting NADW formation rates for the LIG similar to modern ones (e.g., Adkins et al., 1997).

However, one possibility that has not been considered up to now is whether Greenland ice sheet meltwater might have contributed to the LSW halt. The extent to which Greenland ice sheet volume might have been reduced during the LIG is relevant to obtaining an estimate of its sensitivity, in particular with respect to potential future global warming. Global sea level during the LIG may have been up to 6–7 m higher than the present level, indicating a significant reduction in global ice volume corresponding to the total of the Greenland or the West Antarctic ice sheets. Cuffey and Marshall (2000) have

recently concluded that probably most of the global sea level change (4.5–5.0 m) was due to a strong reduction in the size of the Greenland ice sheet. An estimate of 5 m over 5 ka would represent a freshwater flux anomaly of ~ 0.01 Sv. This represents a very modest perturbation. Yet, the melting was strongest in southwest Greenland, closest to the Labrador Sea, and thus could potentially have affected LSW formation.

Conclusions and Discussion

Paleoclimatic reconstructions suggest widespread evidence for warmth during the LIG, especially at mid–high northern latitudes. Climate models provide plausible explanations for this warmth. Models of different complexities show a number of common features, such as enhanced JJA SAT warming over the continents leading to strengthened monsoons and high northern latitude warming throughout the year. Focusing on the Northern Hemisphere, where most of the paleodata are located and the response of the models is largest, the best agreement is found in JJA. This is consistent with the fact that

summer temperatures reflect the direct thermodynamic response to insolation changes. The DJF response, however, involves changes in dynamics. This leads to deviations in the SAT response from the direct thermodynamic response and, thus, to discrepancies between models of differing degrees of complexity and with different representations of the dynamics: while the simpler models reflect mainly the direct thermodynamic response to insolation changes, the more complex models suggest changes in the atmospheric dynamics reflecting an intensification of the AO. Through enhanced westerlies over the North Atlantic, this results in enhanced moisture and heat advection into Eurasia, which together with the sea-ice albedo–SST feedback could provide an explanation for warmth during the LIG, relative to the present, found especially at the mid- and high northern latitudes in northern winter. Yet, another possibility suggested by simpler models including interactive vegetation modules, and especially relevant at mid–high northern latitudes, is that feedbacks related to vegetation might also have played an important role. This hypothesis is supported by the evidence for boreal forests expanding further north during the LIG. Thus, the exact interplay of dynamics and biosphere during the LIG needs further clarification. The advent of comprehensive models including dynamic biosphere components will hopefully contribute to this purpose.

Acknowledgments

I am grateful to F. Kaspar for kindly providing me the figure on temperature departures simulated by their model, to J. F. González-Rouco and S. Marshall for discussions and comments which have contributed to improve this manuscript, and to the anonymous reviewer for instructive comments. M. Introduction

General circulation models (GCMs) are valuable tools for developing a quantitative understanding of climate dynamics and climate change, and studies conducted using GCMs have provided important insights into the climate of the Last Glacial Maximum (LGM). The term ‘GCM’ is typically used to describe a numerical model in which the temporal evolution of the three-dimensional circulation of the atmosphere, ocean, or both is determined by solving the set of coupled, partial differential equations governing fluid motion. The equations are sufficiently complex that analytic solutions do not exist, and thus the equations must be solved by numerical methods. The atmosphere and ocean are divided into grid boxes, and the equations are solved for each of the boxes. Because the typical dimensions of a grid box are 100–400 km in the horizontal and 10–200 m (ocean) or 50–2000 m (atmosphere) in the vertical, a global GCM will have 10^5 – 10^6 grid boxes. The numerical solution of the equations governing fluid motion for this large number of grid boxes requires substantial computing power. Washington and Parkinson (2005) provided a detailed description of GCMs and their construction.

GCMs are among the most comprehensive members of the more general category of climate models. Simpler climate models reduce the complexity of the climate system, most often by averaging over one or more spatial dimensions. Although such simpler climate models have been useful in understanding Quaternary climate change, they are not the focus of this article. Instead, the focus is limited to results that have been obtained with the following types of climate models, listed in order of increasing complexity: atmospheric GCMs using prescribed sea-surface temperatures (SSTs) as a lower boundary condition, atmospheric GCMs coupled to highly simplified models of the ocean-mixed layer, and atmospheric GCMs coupled to oceanic GCMs. The decision to narrow the focus is made in order to keep the scope of this article manageable and to recognize the historical importance of these models.

Types of GCMs

Atmospheric GCMs with prescribed SSTs were used in the earliest attempts to model glacial climate, and were made possible by the pioneering work of the CLIMAP Project (1981) in reconstructing the global SST distribution for the LGM. Such models greatly simplify the interaction between the atmosphere and ocean by eliminating the influence of the atmosphere on the ocean, but can be useful in determining how the atmospheric circulation and land-surface climate might respond to a given set of surface boundary conditions. An important weakness of atmospheric GCMs with prescribed SSTs is that they do not conserve energy. The ocean can serve as

an infinite source or sink of energy, with a compensating energy flux at the top of the atmosphere. In a specific example, LGM simulations with atmospheric GCMs using SSTs prescribed according to Climate: Long-range Investigation, Mapping, and Prediction (CLIMAP) typically are in radiation deficit, with emitted radiation at the top of the atmosphere exceeding incoming radiation. If the atmospheric component of the model is assumed to be realistic, the radiation deficit would imply that the SSTs are too warm in an aggregate sense, as cooling would ensue if the SSTs were no longer constrained. Alternatively, the SSTs could be correct and the radiation deficit could result from deficiencies in the atmospheric model.

Atmospheric GCMs coupled to highly simplified models of the ocean-mixed layer alleviate the need for the global distribution of SST as a prescribed lower boundary condition. In these models, sometimes called atmosphere-mixed layer ocean models, the upper ocean is represented by a motionless slab of water of uniform temperature. (Such models are also known as atmosphere-slab ocean models in recognition of the simplicity with which the upper ocean is represented.) Atmosphere-slab ocean models, which typically include a sea-ice model in which ice can form or melt in response to thermodynamic processes, improve upon models with prescribed SSTs by allowing a two-way thermodynamic interaction between the atmosphere and the ocean. SST is an output variable in this type of climate model, which facilitates comparisons with reconstructions of glacial climate. The simplified ocean does not represent the effects of ocean circulation or thermal communication between the mixed layer and the deep ocean. In most atmosphere-slab ocean models, an artificial heat flux (often called a ‘q-flux’) is prescribed at each ocean grid point in order to represent the convergence or divergence of heat that would result from ocean heat transport in the real climate system. The inability to simulate changes in ocean heat transport or the dynamical interactions between the atmosphere and ocean (e.g., wind-driven ocean circulation or changes in ocean circulation resulting from density changes due to buoyancy fluxes) is a significant limitation of atmosphere-slab ocean models.

The coupling of an atmospheric GCM with an oceanic GCM yields a more complete model of the climate system with the capability of simulating changes in circulation in the ocean as well as the atmosphere. Because such coupled atmosphere–ocean GCMs (AOGCMs) can simulate two-way dynamic and thermodynamic interactions between the atmosphere and ocean, they can simulate coupled modes of climate variability such as the El Niño–Southern Oscillation (ENSO) phenomenon, a quasiperiodic fluctuation in the temperature of the central and eastern equatorial Pacific with far-ranging implications for climate. They can also simulate changes in the intensity of coastal upwelling in regions induced by changes in surface winds, or changes in ocean overturning (i.e., the so-called ocean conveyor; Broecker, 1991), that result from changes in the fluxes

of heat and fresh water. The additional realism of AOGCMs comes with a cost, however. Because the equations governing fluid motion must be solved for both the atmosphere and the ocean, and the long timescales ($\sim 10^3$ years) of the deep ocean circulation require AOGCMs to be integrated longer before they fully adjust to the forcing, AOGCMs require substantially greater amounts of computer time than atmosphere-only or atmosphere-slab ocean GCMs.

Design of GCM Experiments

For past epochs in which the climate was substantially different from today, such as the LGM, there are differences in atmospheric composition, Earth–Sun geometry, continental configuration, solar irradiance, or surface characteristics that are capable of altering the radiation balance, either locally or globally. Climate model simulations are conducted by altering one or more of these characteristics and comparing the resulting climate to a simulation of modern climate. Some of these changes, such as Earth–Sun geometry, continental configuration, and solar irradiance, are clearly external to the climate system. Others, such as atmospheric composition or the spatial distribution of continental ice sheets, are influenced by processes internal to the climate system.

A useful paradigm for thinking about the design of climate model experiments is the distinction between external forcing and internal feedbacks. Internal feedbacks are climate system processes that are explicitly represented within the model, whereas external forcing involves processes that are not represented in the model. A change that occurs outside the climate system, such as an increase in the brightness of the Sun, is considered to be an external forcing in this paradigm. The growth and decay of large continental ice sheets would also be an external forcing in most GCMs, because they do not include glacial dynamics. In a more comprehensive model that includes glacial dynamics, ice-sheet growth and decay would be an internal feedback. An unavoidable consequence of this paradigm that some may find counterintuitive is that whether a process is considered to be an external forcing or an internal feedback depends upon the construction of the model.

As an example, atmosphere-only GCMs require that the global distribution of SST and sea ice be specified. When simulating the LGM climate with such a model, the changes in specified SST and sea ice should be regarded as an external forcing. Thus, atmosphere-only GCMs cannot be used to understand the processes that led to changes in SST and sea ice during the LGM, but they can be used to simulate the atmospheric circulation and the spatial distribution of precipitation

that would accompany the specified changes in SST, sea ice, and other external forcings. Such models have also been useful for simulating the transport of isotopic tracers in water and the location and intensity of storm tracks during the LGM.

Atmosphere-slab ocean GCMs and AOGCMs do not require the specification of SST and sea ice, allowing them to be used when the objective is to determine if a model can simulate realistic changes in temperature in response to LGM external forcings (e.g., Manabe and Broccoli, 1985a). Such simulations allow the realism of internal feedbacks within the model to be evaluated, at least to the extent to which LGM temperature changes can be constrained by paleodata. Similarly, models that determine changes in temperature internally can be useful in understanding the mechanisms responsible for spatial variations in LGM cooling.

The external forcings that are relevant to most LGM simulations with atmosphere-slab ocean GCMs and AOGCMs are changes in atmospheric composition (including greenhouse gases and mineral dust), Earth–Sun geometry (i.e., Earth’s orbital parameters), continental ice-sheet distribution, sea level, and vegetation (Table 1). (Recall that changes in atmospheric composition, ice-sheet distribution, and vegetation are considered external forcings because most GCMs do not include biogeochemical cycling, glacial dynamics, or interactive vegetation.) Concentrations of greenhouse gases at the LGM are known from ice-core evidence, and orbital parameters for that time can also be calculated very accurately, making both of these forcings very well constrained. Sea-level changes are also relatively well known from multiple lines of evidence. Glacial geology provides reliable information about continental ice margins at the LGM, although there are larger uncertainties regarding LGM ice sheets that terminate on the now-inundated continental shelves. Ice-sheet thicknesses can be inferred from glacial geology and inverse modeling of postglacial isostatic adjustment, but with considerable uncertainties. The largest uncertainties involve vegetation changes and mineral dust concentrations. Insufficient data exist to develop a global vegetation map for the LGM, although there is ample evidence of vegetation changes on local and regional scales. Data from ice and sediment cores indicate increased dust deposition during the LGM, but these data are insufficient to construct a reliable three-dimensional distribution of atmospheric dust concentrations, although some estimates are available from model simulations.

The importance of various external forcings in contributing to the LGM climate can be quantified in terms of the radiative forcing (Table 1). Radiative forcing is the hypothetical change in the global mean radiative balance that would result from changing a particular forcing instantaneously without allowing

Table 1 Climate forcing mechanisms for the Last Glacial Maximum (LGM)

<i>Climate forcing mechanism</i>	<i>Radiative forcing</i>	<i>Confidence</i>	<i>References</i>
Greenhouse gases	-2 to -3 W m^{-2}	Very high	Hansen et al. (1993), Hewitt and Mitchell (1997), and Broccoli (2000)
Continental ice sheets	-2 to -3.3 W m^{-2}	Moderate	Hansen et al. (1993), Hewitt and Mitchell (1997), and Broccoli (2000)
Orbital parameters	$\pm 0.2 \text{ W m}^{-2}$	Very high	Hewitt and Mitchell (1997) and Broccoli (2000)
Sea level	-0.3 to -0.5 W m^{-2}	Moderate	Hewitt and Mitchell (1997) and Broccoli (2000)
Vegetation	0 to -1 W m^{-2}	Low	Crucifix and Hewitt (2005)
Atmospheric dust content	-1 to -2.3 W m^{-2}	Low	Hansen et al. (1993) and Claquin et al. (2003)

the climate system to respond. (For reasons that are beyond the scope of this article, radiative forcing is most commonly evaluated at the tropopause, which is the top of the 10–15 km deep atmospheric layer that undergoes efficient thermal communication with the surface.)

Some of the LGM radiative forcings can be quantified with relatively modest uncertainties. The two largest sources of radiative forcing of the Ice Age climate are the reduction in atmospheric greenhouse gas concentrations and the expansion of continental ice sheets, both of which are negative. Of the former, most of the forcing comes from the glacial reduction in carbon dioxide, with additional contributions from methane and nitrous oxide. Radiative forcing from the expanded LGM ice sheets is confined to the regions covered by continental ice, and is particularly intense near the southern margins of the Laurentide and Eurasian ice sheets where solar radiation (and hence reflection) is especially strong. The reduction in sea level at the LGM induces a modest negative radiative forcing, as the additional land areas have a higher surface albedo than the ocean surface. The radiative forcing due to the changes in orbital parameters is very small, despite the importance of orbital forcing for ice-sheet growth and decay, because of the similarity between the modern and LGM orbital configurations.

The radiative forcings contributed by changes in vegetation and atmospheric dust content are much more difficult to quantify. The global distribution of LGM vegetation is not known with any certainty, although there have been attempts to map it (Adams and Faure, 1997). One might expect that the magnitude of the radiative forcing from vegetation changes would be limited by some compensation between regions of increased and decreased surface albedo, but constraints are relatively weak. The uncertainties associated with reconstructing the global three-dimensional distribution of atmospheric dust concentration preclude a well-constrained value for dust forcing, and additional uncertainties in the optical properties of mineral dust add to the problem. Nonetheless, it has been estimated that LGM dust may contribute a substantial negative forcing, perhaps only exceeded by the greenhouse gas and ice-sheet forcings.

Results from GCM Experiments

GCM simulations of glacial climate have been conducted in substantial numbers, making it impractical to describe the findings from all of them in detail. There are, however, certain climate processes that have received special attention, and they are discussed in this section. A brief summary of these results is provided in Table 2.

Interhemispheric Asymmetry of Cooling

Virtually all LGM climate simulations are characterized by greater cooling in the Northern Hemisphere, particularly in the immediate vicinity of the ice sheets, but also extending over the subpolar and mid-latitude North Atlantic in many cases. In contrast, simulated cooling tends to be smaller in the tropics and at comparable latitudes of the Southern Hemisphere. The large cooling over the ice sheets has multiple causes. The high albedo of ice-covered surfaces results in

Table 2 Summary of changes in climate from GCM simulations of the LGM

<i>Spatial distribution of cooling</i>	<i>Largest cooling over Laurentide and Eurasian ice sheets; Northern Hemisphere cools more than Southern Hemisphere</i>
Atmospheric circulation	Polar jet stream splits around Laurentide ice sheet; enhanced ridge of high pressure in upper troposphere over western North America
Monsoons	Weakening of the South Asian monsoon; weakening of cross-equatorial flow in the Indian Ocean; decrease in intensity of south westerly winds over the Arabian Sea
Tropical cooling	Models simulate overall tropical cooling; magnitude varies among different models
Meridional overturning circulation	Weakens in two models and strengthens slightly in another; North Atlantic Deep Water does not sink as deep
Tropical Pacific climate and air–sea interactions	Amplitude of ENSO variability is increased in one model; mean climate becomes more ‘La Niña-like’ in two others

decreased absorption of solar radiation. Ice-sheet surfaces at the LGM were elevated in some locations by more than 2 km, with attendant cooling due to the decrease of temperature with height in the troposphere. Ice-covered surfaces also limit summer warming, as the latent heat required by surface melting acts as an energy sink.

The advection of cold air that originates over the ice sheets contributes to cooling in proximity to the ice sheets, allowing the cooling effects of the ice sheets to spread beyond their boundaries. When the atmospheric circulation carries ice-cooled air across the ocean surface, as in the North Atlantic, it can promote sea-ice growth, which further cools the atmosphere by reflecting solar radiation and insulating the atmosphere from the relatively warm ocean waters below (Manabe and Broccoli, 1985b). Experiments in which only the ice-sheet forcing was employed indicate that the thermal effects of continental ice sheets are primarily confined to the Northern Hemisphere, and thus constitute the primary cause of interhemispheric asymmetry in the magnitude of simulated LGM cooling. Some recent studies suggest that this asymmetry is capable of altering the atmospheric circulation in the tropics, leading to changes in the pattern of tropical precipitation (Chiang et al., 2003).

Alteration of the Northern Hemisphere Jet Stream

Some of the earliest simulations of LGM climate found that the expanded ice sheets of the Northern Hemisphere were capable of substantially altering the atmospheric circulation. Because the ice sheets can extend as much as 2–3 km above sea level, they act as topographic barriers to the circulation. The location of the ice sheets in the path of the polar jet stream creates the potential for the jet to be altered by their presence.

In simulations of the LGM climate, [Kutzbach and Guetter \(1984\)](#) and [Manabe and Broccoli \(1984\)](#) found that the polar jet stream was split into two branches by the Laurentide ice sheet. One branch skirted the southern edge of the ice sheet, and the other curved anticyclonically along its northern periphery.

The presence of the Laurentide ice sheet also amplified the upper tropospheric ridge of high pressure that is found over western North America in winter, enhancing southerly flow into what is now Alaska and producing modest LGM winter warming. The combination of the enhanced upper tropospheric ridge and the northern branch of the split polar jet stream facilitated the export of cold air to the North Atlantic, as discussed in Section ‘[Interhemispheric Asymmetry of Cooling](#).’ The southern branch of the jet enhanced winter precipitation in southwestern North America, leading to a wetter climate there.

More recent simulations of LGM climate have used a reconstruction of glacial topography in which the surface elevations of the ice sheets are somewhat lower than in the earlier simulations. This reduction in surface elevation reduces the barrier effect of the Laurentide ice sheet, with an attendant reduction in the degree to which the polar jet stream splits, although the resulting circulation is qualitatively similar to the results from the earlier simulations.

Monsoons

The nonuniform cooling in LGM simulations has an impact on monsoon circulations, particularly those in the Northern Hemisphere. [Prell and Kutzbach \(1987\)](#) identified a weakening of the South Asian monsoon system in their simulation of LGM climate with an atmosphere-only GCM. The weakening of the South Asian monsoon, which was attributed to a reduction of land temperatures during boreal summer, was accompanied by weaker cross-equatorial flow in the Indian Ocean and a decrease in the intensity of monsoon-related southwesterly winds over the Arabian Sea. More recent model simulations with atmosphere-slab ocean GCMs and AOGCMs produce a similar response, although the details of the circulation changes can be somewhat different because the SST pattern simulated by these models does not exactly correspond to the CLIMAP pattern used by [Prell and Kutzbach \(1987\)](#).

The glacial monsoon response is consistent, in terms of its physical mechanism, with other climate model simulations that indicate a strong response of the Asian monsoon to precessional forcing. The monsoon is strong when the phase of the precession cycle is such that perihelion occurs in boreal summer, which increases continental temperatures and the land–sea temperature contrast. The monsoon is weaker when perihelion occurs in winter, since this orbital configuration results in cooler summer temperatures, analogous to the glacial case.

Tropical Cooling

The magnitude of tropical cooling during the LGM has been a source of controversy for quite some time. The original reconstruction of glacial SSTs by CLIMAP indicated little or no cooling over large areas of the tropics and subtropics. Apparent

inconsistencies between relatively warm tropical SST and indicators of larger cooling from the tropical continents (snow-line depression, noble gases in aquifers, and pollen) have prompted questions about the actual magnitude of LGM tropical cooling (e.g., [Broecker, 1995](#); [Rind and Peteet, 1985](#)). More recent proxies for SST such as alkenone unsaturation and Mg/Ca ratio indicate that LGM tropical cooling was larger than the CLIMAP reconstruction.

Virtually, all LGM simulations with atmosphere-slab ocean GCMs or AOGCMs have simulated reduced temperatures throughout the tropics, although magnitudes vary among model simulations. Using a number of simulations performed within the framework of the Paleoclimate Modeling Intercomparison Project (PMIP), [Pinot et al. \(1999\)](#) found that all atmosphere-slab ocean GCMs examined produced cooling over the Indian and Pacific Oceans that contrasted with the very limited cooling indicated by CLIMAP. For roughly half of these simulations, the simulated terrestrial cooling in the tropics was in good agreement with paleodata. Focusing on the results of one particular PMIP simulation, [Broccoli \(2000\)](#) found that the simulated cooling was consistent with some tropical temperature proxies, but smaller than the cooling inferred from other proxies. He also noted that the differences in tropical cooling estimates based on different proxies were relatively large, precluding the use of tropical paleotemperatures as a conclusive test of climate models.

Recent LGM simulations with AOGCMs indicate that dynamical processes such as the ventilation of thermocline and intermediate waters from higher latitudes ([Liu et al., 2002](#)) can also influence the magnitude to tropical cooling, at least locally or regionally. Changes in wind stress and concomitant equatorial upwelling are thought to be responsible for enhanced cooling in the eastern equatorial Pacific in [Hewitt et al. \(2001\)](#).

Meridional Overturning Circulation in the Ocean

The advent of AOGCM simulations of the LGM has opened new areas of investigation for climate modelers. A particular focus of AOGCM simulation studies has been the response of the meridional overturning circulation (MOC) in the ocean to glacial forcing. The MOC, which is also known as the thermohaline circulation because it is thought to be driven by the effects of temperature and salinity on the density of sea water, is a global circulation system in which cold, salty surface waters sink in the subpolar North Atlantic, forming North Atlantic Deep Water (NADW), which spreads throughout the global ocean at depth before gradually upwelling into the thermocline.

Paleoceanographic evidence from the LGM indicates that NADW did not sink as deep as it does today, and there is some evidence that the overall volume of water involved in the MOC may have been less, although the latter interpretation remains somewhat controversial. Thus, there is an understandable interest in developing further insights into this question based on the results from glacial AOGCM simulations.

The behavior of the MOC in AOGCM simulations of the LGM varies. In an experiment with the Hadley Centre model HadCM3 ([Hewitt et al., 2001](#)), the MOC intensified and was accompanied by an increase in northward heat transport in the North Atlantic, producing relatively warm SSTs in parts of that ocean. Studies with the National Center for Atmospheric

Research model CSM (Shin et al., 2003) and the Canadian Centre for Climate Modeling and Analysis (CCCma) model (Kim et al., 2003) reported a weakening of the MOC and a reduction in the downward penetration of NADW. The weakening of NADW formation and the MOC in CCSM was attributed to changes in Antarctic Bottom Water formation that result from the expansion of sea ice in the Southern Ocean.

At present there is no definitive explanation for the difference between the HadCM3 response and that of the other models, although it is possible to speculate that HadCM3 had not completely adjusted to LGM forcing. It is worth noting that both HadCM3 and the CCCma model (Kim et al., 2002) experienced a transient increase in MOC intensity immediately after the LGM forcing was initiated, but the CCCma model eventually settled in a state with a weaker MOC.

Tropical Pacific Climate and Air–Sea Interactions

Air–sea interactions in the tropical Pacific Ocean give rise to the ENSO phenomenon. The warm phase of ENSO, known as El Niño, is characterized by an anomalous warming of the central and eastern equatorial Pacific, and SST anomalies have the opposite sign during the cold, or La Niña phase. In many parts of the world, primarily in the tropics, ENSO is the largest source of interannual climate variability.

The importance of ENSO in the modern climate has led many to wonder if ENSO variability was different in past climates. Recent AOGCM simulations provide some insights regarding the LGM. Otto-Bliesner et al. (2003) found that the amplitude of ENSO variability was enhanced during the LGM. Weakening of the zonal SST gradient, wind stresses, and upwelling in the tropical Pacific region and an intensification of the tropical thermocline were identified as causes of this enhanced variability. Other investigators have noted changes in the mean climate of the tropical Pacific, with the SST distribution being more La Niña-like (i.e., greater cooling in the eastern equatorial Pacific than in locations farther west) in the simulations by Hewitt et al. (2003) and Kim et al. (2003). The implications of these changes in mean climate on the amplitude of ENSO variability in these models are unknown.

Future Directions

Increases in computing power and experience with running AOGCMs are allowing these models to become more widely applied in studies of glacial climate. A number of challenges continue to exist, such as identifying the best way to initialize glacial AOGCM simulations and determining when a model was settled into a representative quasiequilibrium climate state. Models of intermediate complexity, in which both atmosphere and ocean are represented by simplified GCMs, can run much faster and should prove useful in guiding the use of full AOGCMs.

An important trend in climate modeling is toward the development of more comprehensive models of the climate system that include atmospheric and ocean chemistry and interactions with the biosphere. This trend is providing new directions to glacial climate simulations. For example, many modeling groups are developing the capability to include

isotopic tracers in AOGCMs, building upon past work that was done using atmosphere-only GCMs (Joussaume et al., 1984). Models that include interactive vegetation have become more common, and there is evidence that vegetation feedbacks can have important effects on LGM climate change on local and regional scales (e.g., Crucifix and Hewitt, 2005).

For simulating the climates of the Quaternary, the ultimate goal may be a model of the earth system that has an AOGCM at its core, but also includes the necessary elements to predict the growth and decay of continental ice sheets, the concentration of greenhouse gases and aerosols (including dust) in the atmosphere, the spatial distribution of vegetation, and the three-dimensional distribution of isotopic tracers in the atmosphere and ocean. A comprehensive model of this kind would allow simulations in which the only forcing comes from the variations in Earth's orbital parameters. The ability to conduct such experiments would represent an important step toward a thorough understanding of the causes of the large temporal variations in Quaternary climate.

Introduction

Teleconnections, such as El Niño, are climatic relationships over long distances that provide predictability of the climate system at interannual to decadal timeframes. They are often expressed as a single number to represent contrasting states of the climate system, often dealing with changes in prominent modes of atmospheric circulation. Teleconnections and their associated climatic changes at interannual and decadal time scales occur at frequencies every 1–100 years (Martinson et al., 1998). An understanding of these teleconnections at these time scales is extremely vital to society because they provide the framework in planning schemes for water resources and agriculture. For example, the monsoons of Asia and Africa affect hundreds of millions of people, with variations of occurrence at shorter time scales approximately every 3–7 years, and severe drought occasionally causing widespread famine.

Climatologists have studied interannual–decadal climatic changes in modern instrumental records, but records normally do not extend farther back than a century for most areas. Also during the twentieth century, anthropogenic climatic change became more apparent, causing some difficulties in disentangling anthropogenic from natural climatic effects such as involving fossil fuel-induced global warming. Therefore, a longer perspective on climatic changes at these short time scales contributes significantly to a further understanding on natural climatic variability and its causes (Overpeck and Webb, 2000). Furthermore, a longer historical perspective of climatic changes at interannual and decadal time scales can aid in analyzing the societal responses to climatic changes. This article describes an overview on what scholars know about the synoptic climatology of teleconnections such as the El Niño phenomena, the current status on how paleoclimatologists are utilizing proxy data to reconstruct these important teleconnections, and some potential forcing mechanisms of past El Niño/Southern Oscillation (ENSO) events.

Teleconnections

ENSO

Clearly, the most important source of interannual climatic variability at the global scale is the ENSO phenomenon. El Niño is defined as an anomalous warming of sea-surface temperatures of approximately 2 °C or more in the central and eastern Pacific Ocean of the Southern Hemisphere (Glantz, 1996). It is named after the ‘Christ Child’ since it usually initially appears around Christmas, off the western coast of South America. Normally, the atmospheric circulation in the South Pacific is characterized by high pressure off western South America and low pressure over Australia. However, during an El Niño year, lower pressure and increased convection are prevalent in the central and eastern South Pacific,

and higher pressure occurs over Australia, thus defining the ‘Southern Oscillation.’ Sea-level pressure differences between Tahiti, Indonesia, and Darwin, Australia define the Southern Oscillation Index (SOI), with abnormally negative SOI values indicating warm events and abnormally positive values indicating cold events. El Niño events, also termed as ‘warm events,’ occur approximately every 3–7 years although some events may occur in back-to-back years or may be lacking for up to a decade. Cold events or La Niña, also generally occur at the same time frequency and are regarded as part of ENSO. La Niña is the opposite condition of El Niño, associated with abnormal cooling of sea-surface temperatures in the central and eastern South Pacific, higher pressure off western South America, and lower pressure over eastern Australia.

During ENSO events, energy exchanges occur between the oceans and atmosphere, causing changes in the Southern Oscillation that eventually affect atmospheric circulation, temperature, and precipitation anomalies elsewhere over the globe. Climatologists have concluded that tropical forcing causes similar teleconnections to reoccur during individual warm and cold events (Kiladis and Diaz, 1989). Composite anomaly maps of 500 mb heights (upper air flow) reveal some generalized synoptic patterns that occur during El Niño (SOI negative) and La Niña (SOI positive; Figure 1). Note that the contrasting SOI extremes do not necessarily reveal completely opposite characteristics for every region. However, some generalizations are clearly apparent for some ENSO-sensitive regions. For example, a trough-ridge-trough pattern is evident over the North Pacific Ocean and adjacent North America during El Niño, while a ridge-trough-ridge pattern appears during La Niña. The increased troughing into the southeastern United States in the El Niño pattern would enable more colder air to penetrate into the region, while the pattern for La Niña indicates ridging over the southeastern United States that would create warmer temperatures. Precipitation responses during El Niño and La Niña also affect some regions with contrasting anomalies (Figure 2). For example, northern Mexico and the southwestern United States tend to be wetter during El Niño but drier during La Niña. Precipitation anomalies over northeastern Brazil indicate drier conditions during El Niño but wetter conditions during La Niña.

Note that some individual ENSO events may cause some climate anomaly patterns that differ from what is normally expected if such an event is of extremely high magnitude. For example, the 1982–83 and 1997–98 El Niños were very strong warm events documented in modern instrumental records, with their global teleconnections differing from many others that are typical of warm events. Furthermore, the relationships between tropical sea-surface temperatures and mid-latitude climate may change through time. We must therefore look at the paleoclimate record to gain a longer perspective of ENSO variability.

Figure 1 Composite anomaly maps of winter 500 mb heights and winds during SOI negative and SOI positive events. Negative anomalies indicate increased cyclonic flow, and positive anomalies indicate increased anticyclonic flow. Data are from the NCEP-Reanalysis Project (Kalnay et al., 1996).

Other Teleconnection Patterns

Two other important teleconnections affecting mid-latitude climate in the Northern Hemisphere at interannual timescales are the North Atlantic Oscillation (NAO) and Pacific North American (PNA) patterns. The NAO shows variation in the strength of the westerlies in the North Atlantic due to variations in the Icelandic low and Azores high (Rogers, 1984). The 500 mb height anomalies of the positive mode of the NAO indicate an anomalously stronger Icelandic low and a weak Azores high (Figure 3). Temperature responses to a positive NAO mode indicate cooler temperatures over Greenland and warmer temperatures over much of central and northern Europe (Figure 4). A weaker Icelandic low and stronger Azores high generally correspond with conditions of the negative mode, with warmer temperatures over Greenland and cooler temperatures over most of Europe (Figures 3 and 4). Variations in the NAO result from changes of North Atlantic sea-surface temperatures and ocean circulation, and perhaps sea ice at higher latitudes. The PNA teleconnection represents variations in mid-tropospheric flow that mostly affects North American climate (Leathers et al., 1991). A positive PNA pattern involves a trough in the east-central North Pacific, a ridge

Figure 2 Composite anomaly maps of winter precipitation rates during SOI negative and SOI positive events. Negative anomalies indicate increased dryness, and positive anomalies indicate increased wetness. Data are from the NCEP-Reanalysis Project (Kalnay et al., 1996).

over western North America, and a trough over eastern North America, and a negative PNA pattern indicates opposite mid-tropospheric flow. Variations in the PNA pattern probably occur due to variations in sea-surface temperatures in the western and equatorial Pacific, and perhaps due to several climatic variables in East Asia.

The Pacific Decadal Oscillation (PDO) is an ‘ENSO-like’ phenomena that exhibits more persistent (decadal) variability as opposed to interannual (Zhang et al., 1997). Its index has been calculated based on Pacific Ocean sea-surface temperatures (Mantua et al., 1997). Positive PDO indices are indicative of colder SSTs in the north central Pacific Ocean and warmer SSTs off the west coast of North America – and negative PDO indices indicate the opposite condition. Its signal is a bit more prominent in the Mid-Latitudes and is probably driven more by sea-surface temperatures in the Mid-Latitudes, though tropical forcing cannot be completely excluded (Latif and Barnett, 1996). The Arctic Oscillation (AO) also generally exhibits somewhat more decadal-type behavior (Thompson and Wallace, 1998). The 500 mb winter composite anomaly maps of both AO modes reveal contrasting atmospheric circulation patterns for the polar regions of the AO, as compared to those at Mid-Latitudes (Figure 5). Winter temperatures during

the positive mode of the AO indicate colder temperatures in Greenland, warmer temperatures over much of Canada, and colder temperatures in Alaska (Figure 6). Temperatures during the negative mode of the AO show warmer conditions over

Greenland and Alaska, but the colder conditions over Canada is not well pronounced. Although these temperature responses of the AO are strongest seasonally in winter, a weaker signal is also evident in summer, which may show up in some paleoclimatic reconstructions (D'Arrigo et al., 2003).

Reconstruction of ENSO

Evidence from historical documents, tree-rings, and corals provides most of the ENSO reconstructions with annual resolution. Reconstructions of premodern ENSO events based on historical evidence have mostly been done in western South America, through the reconstruction of warm events (Ortlieb, 2000). Also, Quinn (1992) constructed a large-scale El Niño chronology by incorporating Nile River flood height data as well as records of droughts and floods in the Middle East and India. These historical reconstructions were each also assigned a relative strength (weak to very strong) and a confidence rating (1–5 with 5 being highest) relating to the reliability of historical evidence. The Quinn reconstruction extends back to AD 622, but the record prior to 1525 is based mostly on the Nile flood data. A comparison between the historical and modern instrumental record since 1877 shows approximately 75% of the El Niño years as being identical. Some anomalies exist, such as the occurrence of heavy rainfall in Peru during a non El Niño year, and some reconstructions may be suspect due to the validity and quality of historical sources (Ortlieb, 2000). Yet, a time series of the Quinn record since AD 622 shows the prevalence of a 2–6-year El Niño cycle that is similar to today.

Some coral records lie within the core area of ENSO activity, with continuous annual records extending back several hundred years (Tudhope et al., 2001). Most coral studies to date primarily analyze $\delta^{18}\text{O}$ isotopes in the skeletal carbonate as sea-surface temperature indicators (Cole, 2003), as $\delta^{18}\text{O}$ can represent seasonal curves within the annual cycle. However, $\delta^{18}\text{O}$ /climate relationships from corals are not simple, as for some areas, increased evaporation can enrich $\delta^{18}\text{O}$; conversely, increased precipitation can decrease $\delta^{18}\text{O}$. In addition, the $\Delta^{14}\text{C}$ in corals has been examined as an indicator of oceanic and atmospheric circulation changes, representative of ENSO events at interannual time scales. The trace elements cadmium and barium are also valuable in coral records, as they represent deep water upwelling conditions that are prevalent, for example, during cool periods of ENSO.

Several reconstructions of the winter SOI have been conducted from tree-rings in western North America and the Southern Hemisphere, by selecting tree-ring sites that are in ENSO-sensitive areas today. Perhaps the strongest and most coherent winter SOI reconstruction from tree rings comes from ENSO-sensitive trees in southwestern North America (Cook, 2000; Stahle et al., 1998). Some of the warm events from the reconstruction closely match the El Niño years from the historical record, but there are numerous disagreements due to non-ENSO climatic responses and problems with some of the historical records. A winter reconstruction of the SOI (Niño 3 region) from a network of tree rings in southwestern North America indicates that interannual variability is still prominent over the last four centuries, but less variability is evident for most of the time before the twentieth century (Figure 7).

The time period between the mid-1700s and early 1800s also appears to have somewhat longer periodicities between ENSO events. Luterbacher et al. (2002) provide a winter reconstruction of the NAO from old instrumental and historical records (Figure 7). The reconstruction reveals that much of the seventeenth to nineteenth centuries were characterized by somewhat less variability than that of the twentieth century, and the recent rise of the last 30–40 years is not evident in magnitude from the earlier record. Extreme values, both positive and negative, also exhibited times of increased frequency and absence, such as the active period of positive NAOs in the mid-nineteenth century. D'Arrigo et al. (2001) provide a reconstruction of the annual PDO (Figure 7). Results indicate somewhat increased decadal variability and generally lower indices prior to 1860. A reconstruction of the summer AO by D'Arrigo et al. (2003) from tree-ring sites in the Arctic Basin reveal mostly lower values prior to 1920, particularly in the late nineteenth century and late sixteenth century (Figure 7). Overall, paleoclimate reconstructions of the NAO, PDO, and AO seem to indicate that the twentieth century is rather anomalous when compared to most earlier records. This is an interesting result, and one that requires further investigation.

A long and well-dated ice-core record with annual resolution from Quelccaya, Peru, documents some past ENSO events (Thompson, 2000). However, the site lies a short distance south of the core region of ENSO activity, and it also may be influenced by Atlantic moisture sources; therefore it may not detect all ENSO events. ENSO reconstructions can also benefit from a multiproxy approach. For example, statistical analyses on several ENSO-sensitive historical, ice-core, and tree-ring records reveals 3–8 year periodicities from all of the records for the last 1000 years, though some longer periodicities are evident. Overall, the ENSO climatic expression did not differ dramatically, compared with variations in the modern record (Diaz and Pulwarty, 1994). Another approach to studying ENSO variability involves assessing the prominent patterns as reflected by empirical orthogonal functions (EOFs) of a multiproxy network (Mann et al., 2000). In their methods, Mann et al. demonstrate close calibration of the EOF that resembles ENSO activity with instrumental data from the modern record. Other evidence, such as from faunas (Sandweiss et al., 2001), flood deposits (Magilligan and Goldstein, 2001), paleoecological evidence from fossil pollen (McGlone et al., 1993), Foraminifera records in the tropical Pacific (Stott et al., 2002), and marine varves in the northeastern Pacific (Anderson et al., 1993), can reconstruct long decadal–century time scale variations of ENSO back through the Holocene and at times even into the late Pleistocene.

Regional Paleoclimatic Responses of Past El Niños and Climatic Forcing Mechanisms

Little work has been done on analyzing the consistency of regional and spatial variations of high resolution paleoclimatic responses to ENSO events prior to the modern record, especially for cold events. Yet, such opportunities exist, as demonstrated by Cole and Cook (1998) that ENSO/drought relationships over the United States have not always behaved consistently over the past 130 years. An interesting approach in

Figure 7 Annual time series of selected teleconnection indices as reconstructed by paleoclimatic data. Also shown are 10-year moving averages (bold line) for the SOI and NAO reconstructions. Data of the paleoclimatic reconstructions used in this paper were taken from the NOAA Paleoclimatology website at <http://www.ncdc.noaa.gov/paleo/paleo.html>.

assessing regional responses to paleo-ENSO events was conducted by Whetton and Rutherford (1994), later updated by Whetton et al. (1996). These studies analyzed statistical relationships between El Niño years from the Quinn record and proxy precipitation records in the Eastern Hemisphere. Statistically significant relationships between low precipitation and El Niño are evident for the Nile River and India since 1770, and it weakens for the Nile River prior to 1770, perhaps due to variations in the quality of historical data. Interestingly, correlations between El Niño and Northern China precipitation

records are not significant during the last century, but are statistically significant from 1525 to 1879. A record from Java suggests wetter conditions during El Niño years, but a statistically significant reversal in this relationships occurred during the 1700s. Such reversals in relationships that involve ENSO may be evident elsewhere around the world.

Numerous studies have analyzed the climatic forcing mechanisms that may drive varying periodicities of ENSO in the past at different time scales. This includes the use of general circulation models to simulate the variability of ENSO in model

years (e.g., for a 1000-year run) to further understand the mechanisms that drive the temporal variations in their phases, magnitude, and frequency. Mann et al. (2005) discussed how modeling efforts reveal the tendency for El Niño conditions to occur in response to volcanic forcing, with combined orbital and volcanic forcing explaining natural interannual variability of ENSO over the last 1000 years. They also describe some aspects of more La Niña type conditions that may have occurred during the Medieval Warm Period. The mid-Holocene has been of interest in determining the controls of ENSO activity, as numerous proxies suggest the likelihood of a prolonged weak ENSO period (Cole, 2001). Modeling efforts have recently been successful in simulating the natural variability of ENSO, and efforts in Holocene simulations that incorporate orbital forcing suggest the potential importance of cooler SSTs (Otto-Bliesner, 1999). At longer millennial time scales up to about 70 000 years ago, variations in greenhouse gases may be important controls of ENSO variability (Stott et al., 2002). The last interglacial, around 125 000 years ago, is also an interesting timeframe for examining paleo-ENSO, as the number of warm events may have been about twice as active as is normal today (Kukla et al., 2002).

Conclusions

Research on the paleoclimate and reconstruction of teleconnections, such as ENSO, the PNA, and NAO, is still in its early stages. Available data for calibrating annual proxies with the instrumental record are mostly restricted to the last 40 years. An understanding of teleconnections at time scales extending back into the Holocene and late Pleistocene will require more proxy data sites and improvements in modeling. However, the available reconstructions serve to illustrate the importance of a longer perspective of understanding paleo-ENSO events and other teleconnections that exhibit different aspects of variability and magnitude not apparent in the modern instrumental record.

Introduction

A global network of meteorological stations and satellite observations documents the world's modern climates. There are far fewer observations of past conditions, and the need to search out – and to understand – archives of past climates means that despite more than a century of work, the knowledge of the history of climate remains sparse. The numbers of paleoclimate observations, however, are growing and filling in the maps needed to document the climate patterns of the past (e.g., [CLIMAP Project Members, 1981](#); [COHMAP Members, 1988](#); [Cook et al., 1999](#); [Mann et al., 1998](#)). In parallel, paleoclimate modeling of ever-increasing sophistication has provided key conceptual advances toward understanding the climate patterns of the past (e.g., [COHMAP Members, 1988](#); [Joussaume et al., 1999](#); [Rind et al., 1986](#)). Through such approaches, the field of paleoclimatology aims to understand the workings of the climate system.

Understanding past climate dynamics first requires reconstructing climate history. Reconstruction is, therefore, the primary work of paleoclimatologists and a two-part exercise. First, evidence for past conditions is accumulated, and second, the evidence is interpreted. The evidence includes biological, chemical, and geological traces of past events that are influenced by climate, such as tree growth and regional vegetation changes; the accumulation of certain elements and isotopes within glaciers, sediments, and the fossil remains of organisms; or the deposition of sediment in glacial moraines, lakes, and oceans. The interpretations range from simple qualitative inference to elegant quantitative estimates including computer-based process simulations. All approaches to paleoclimatic reconstruction rely on understanding the relationship between climate and the source of evidence; otherwise, the evidence

that exists equals only an unknown weather gauge: does it measure rainfall, temperature, or wind?

Paleoclimate reconstructions have been used as inputs to run computer climate model simulations of past conditions (e.g., sea-surface temperatures reconstructed by [CLIMAP Project Members, 1981](#), have been used by many studies) and have been used to test the accuracy of model output. Comparisons of empirically based reconstructions with model output also reveal the ways that atmospheric and ocean circulation, surface energy and moisture conditions, and other aspects of the climate system shaped past climates (e.g., [COHMAP Members, 1988](#)).

This article presents an overview of the approaches used to reconstruct paleoclimates. The first section introduces the wide range of paleoclimate data sources available. The second and third sections address qualitative and quantitative paleoclimate reconstructions, respectively, along with their utility and problems. The fourth section covers the important step of synthesizing and mapping paleoclimate data, as well as comparisons with climate model output, in order to better understand the nature of changing climatic gradients. Reconstructions alone cannot explain the observed changes. Models are required to understand the processes involved. Only paleoclimate reconstruction, however, can provide a long-term baseline for understanding modern and future conditions and can validate the ability of climate models to simulate conditions unlike those that are experienced today.

Proxies: Where Does Our Data Come From?

Evidence of past climate conditions come from many different sources. These sources can generally be divided into classes

based on the types of phenomena involved (i.e., biotic, geomorphic, geochemical, or geophysical) and according to the temporal resolution of the data (i.e., annual, decadal, centennial, millennial, or multimillennial) (for more details and examples, see [Bradley, 1999](#)). The sources derive from Earth processes that are controlled by climate and the evidence left by these processes acts as a stand-in, or proxy, for actual measurements of past conditions. In paleoclimatology, a proxy record tracks a phenomenon, such as changes in terrestrial vegetation composition, thought to have been closely shaped by climate and, therefore, providing a substitute for a direct measurement of climatic conditions. Proxies range from landscape features (e.g., glacial moraines, dry lake beds and abandoned shorelines, and inactive and vegetated dunes) to carefully calibrated measurements of biotic, geochemical, and geophysical phenomena (e.g., tree-ring widths, glacial ice isotopic values, and borehole temperatures).

Proxy data represent the world in different ways depending on the climatic factors that control the formation of each individual proxy. Multiple lines of evidence, therefore, produce the most complete paleoclimatic reconstructions including both temperature and moisture levels. The sections below briefly address the history of different paleoclimate studies, and consider some of specific proxies that are widely used today.

Qualitative Approaches

Beginnings

Paleoclimate reconstruction began, like many other fields, in a qualitative mode. Louis [Agassiz \(1840\)](#) recognized that hills and ridges of unconsolidated boulders, cobbles, and fine sediment, striations on smoothly worn bedrock and erratic boulders, among other features, represented the deposits left by once-expansive glaciers. Agassiz interpreted these features as glacial moraines left at the margins of flowing glacial ice, the patterns of glacial erosion of bedrock, and boulders transported by ice (rather than Biblical flood waters as others had contended) because he found strong similarities between these landscape features and the features of places that were currently glaciated in the Alps. Thus, Agassiz pioneered an important aspect of paleoclimate reconstruction using modern conditions or places as analogs for past conditions or the character of ancient landscapes. He proposed past 'Ice Ages' with large continental ice sheets based on extensive deposits in Europe and North America that he interpreted through analogy to be glacially derived.

Others followed Agassiz's approach. Another important example of early qualitative inferences about past conditions was the discovery of periods of wetter-than-modern climates in desert regions. [Gilbert \(1890\)](#) described extensive shorelines and river deltas that stood dry at high elevations on mountain sides above the Great Salt Lake in Utah (USA). The best explanation was that the lake had once been much higher than it is today and that the climate of Utah once had been wet. Similar studies recognized large ancient (now dry) lakes throughout the western United States, Australia, and Africa ([Street and Grove, 1979](#)). Conversely, vegetated and inactive dunes, as well as soils and paleosols, in the Great Plains and other regions (e.g., [Forman et al., 2001](#)) have long been interpreted as

signs of different-than-modern conditions in the past. Studies of loess sequences and river terraces have also long been studied as important qualitative signs of past climates that were different than today (e.g., [An et al., 1990](#)).

Continued Utility of Qualitative Approaches

Qualitative approaches to paleoclimate reconstruction remain important today, despite the advances of more quantitative approaches, and have been improved greatly by the development of radiocarbon and other dating methods. For example, the ages of many moraines are now known from the last glaciation because associated organic matter (e.g., logs and peat) have been radiocarbon dated. Maps of glacial extent over time provide vital data to the understanding of how conditions have changed (e.g., [Dyke and Prest, 1987](#)). For example, detailed maps of glacial extent help to inform studies which seek to explain the causes of abrupt climate change, including numerous century- and millennial-scale changes in temperature during the Pleistocene (e.g., [Rind et al., 1986](#)). Thus, long-used qualitative approaches to reconstructing past conditions merge well with late-twentieth and early-twenty-first century advances in paleoclimatology.

Qualitative data have also been important for appropriately parameterizing and testing computer model simulations of climate. Glacial coverage strongly influences the amount of energy coming into the Earth system from the sun because bright white snow has a high albedo, and thus, maps of glacial extent have become important inputs, or 'boundary conditions,' for computer simulations of 'Ice Age' conditions (e.g., [COHMAP Members, 1988](#)). Likewise, maps of lake status based on qualitative reconstructions of past lake shoreline levels, not unlike those initially conducted by [Gilbert \(1890\)](#), provide an important check on whether or not climate models accurately simulate past patterns of moisture balance (e.g., [COHMAP Members, 1988](#)). Similarly, qualitative reconstructions of temperature have been made from the past elevations and latitudes of treeline in mountains and polar regions (e.g., [MacDonald et al., 2000](#)) and have provided important benchmarks for evaluating climate-model simulations representing conditions as recent as the mid-Holocene (e.g., [Joussaume et al., 1999](#)) and as ancient as the Eocene when much of the Arctic was forested (e.g., [Sloan and Barron, 1990](#)).

Current Qualitative Techniques

As noted earlier, many qualitative approaches remain widely used and often focus on the recognition and dating of important landscape features. However, qualitative paleoclimate reconstruction has expanded to include the interpretation of many quantitative paleoenvironmental measurements.

Many climate proxies are precisely measured values of aspects of lake sediment, ocean sediment, or ice cores collected from key locations around the world. The interpretation of these proxies, however, is often qualitative. Examples include inferences about:

- past temperatures from lake sediment core characteristics, such as the amount of organic matter or biogenic silica produced by diatoms, thought to represent changes in

aquatic productivity governed by temperature (e.g., [Levesque et al., 1993](#));

- past temperatures from fossil pollen records of vegetation change, based on assumptions about the controls on plant distributions (e.g., shifts in tree cover during the Younger Dryas Chronozone, ~12 900–11 600 calendar years before present (cal yr BP; [Rind et al., 1986](#));
- past temperature and moisture levels from isotopic values of ice, lake sediment, and marine fossils thought to be closely governed by temperature- or evaporation-dependent effects on isotopic fractionation (e.g., the oxygen isotopic records from the Greenland Summit, beginning with [Dansgaard et al. \(1971\)](#), have been widely used as an uncalibrated record of past temperature);
- past moisture levels from aquatic plant macrofossil assemblages, sediment grain size, and unconformities in lake sediment cores thought to represent changes in lake water level (e.g., [Digerfeldt, 1986](#));
- past moisture levels from oceanic sediment characteristics thought to represent changes in river discharge (e.g., [Peterson et al., 2000](#));
- past moisture levels from sequences of soil development in loess deposits, such as those brought on by periods of intense monsoon rainfall ([An et al., 1990](#));
- past wind speeds and directions, as well as atmospheric pressure gradients, based on changes in lake and ocean sediment composition thought to have been influenced by terrestrial dust inputs, oceanic upwelling, and other wind-driven phenomena (e.g., [Clemens et al., 1991](#));
- past wind speeds and directions, as well as atmospheric pressure gradients, based on changes in the elemental and isotopic chemistry of ice cores thought to have been controlled by the deposition of wind-born dust and sea salt (e.g., [O'Brien et al., 1995](#));
- past frequencies of storm events based on coarse sediment layers deposited in lakes, coastal lagoons, salt marshes, and mangrove swamps thought to represent sediment deposited during floods (e.g., [Donnelly et al., 2001](#)).

Limitations

Qualitative paleoclimate reconstructions can be limited in their utility simply because they do not record the absolute magnitude of past temperature or precipitation changes. This caveat is more complex, however, than the simple lack of quantitative values. Misinterpretations can emerge from studies that do not explicitly calibrate the response of proxies to their governing factors. Many proxies behave in complex ways and can have multiple controls. Attempting to quantify an interpretation has the benefit of establishing the relationship between the proxies and the factors that control it.

Quantitative Approaches

General Concepts

Four types of quantitative paleoclimate reconstructions have received a large amount of attention. First, tree-ring measurements have offered a widely useful tool for quantifying past conditions because tree-ring growth is generally governed

by climate. Local relationships between growth and climate conditions can be calibrated and verified using the overlap between recent growth patterns and actual climate measurements for the same region ([Fritts, 1976](#); [Hughes et al., 1982](#)). Second, paleoclimate conditions have been inferred from assemblages of micro- and macrofossil remains of organisms preserved in ocean, lake, mire, and soil sediments by quantifying modern spatial relationships between the biota and climate and then assuming the same relationships governed past biotic changes (e.g., [Imbrie and Kipp, 1971](#); [Webb and Bryson, 1972](#)). Third, geochemical records have been used to provide quantitative records of climate by also applying calibration functions based on modern conditions, and/or the current understanding of the chemistry, to the proxy records (e.g., [Brassell et al., 1986](#); [Emiliani, 1966](#)). Fourth, physical measurements of temperature from boreholes in rock and ice have yielded quantitative estimates of surface temperatures based on the physics of heat flow (e.g., [Dahl-Jensen et al., 1998](#)).

Quantitative methods initially developed with a focus on fossil and subfossil remains of organisms and were explored in parallel for multiple settings and proxies (e.g., tree-rings foraminifera in ocean sediment cores and pollen in lake sediment cores). Tree-ring records extend back through the entire Holocene, but their application has been especially useful for studies of the past few centuries (e.g., [Mann et al., 1998](#)). Regressions between tree growth and historic climate values stand out as a relatively intuitive approach to tracking past conditions, but complications arise from the multiple local (soil, aspect) to regional (macroclimate) factors involved and from standardization of tree-ring widths to account for changes in tree volume over time ([Fritts, 1976](#)). Tree-ring-based methods incorporate a wide range of statistical methods to deconvolve the climatic signal in ensembles of tree-ring records (e.g., [Hughes et al., 1982](#)) and to map spatial patterns of climate using limited tree-ring data (e.g., [Cook et al., 1999](#)).

An important advance for many other types of biotic remains was the multivariate approach presented by [Imbrie and Kipp \(1971\)](#). The Imbrie and Kipp technique enabled investigators to reconstruct sea-surface temperatures from compositional analyses of foraminifera assemblages in ocean sediment cores based on the development of 'ecological' equations that relate assemblages to their living conditions today and then apply the equations to fossil assemblages. The method was then adapted for use with fossil pollen assemblages (e.g., [Webb and Bryson, 1972](#)) and many advances and additional applications to other taxa followed. Today, multivariate statistical methods are used to infer paleoclimate conditions from the assemblages of (1) many different types of marine, lacustrine, and mire organisms (e.g., [Charman, 2001](#); [Koç Karpuz and Schrader, 1990](#); [Smith, 1993](#)), (2) pollen from terrestrial vegetation (e.g., [Bartlién and Whitlock, 1993](#); [Guiot, 1990](#)), and (3) beetles and other terrestrial organisms (e.g., [Atkinson et al., 1986](#)).

Geochemical techniques also arose from a long history of investigation into the relationships between climate and geochemical systems. Early advances showed the influence of temperature on the relative abundance of light versus heavy isotopes of oxygen and hydrogen in many settings, including minerals and precipitation ([Dansgaard, 1964](#); [Urey, 1947](#)), and measurements of oxygen isotope ratios for paleoclimate

reconstruction followed (Dansgaard et al., 1971; Emiliani, 1966; Stuiver, 1968). The list of modern geochemical techniques includes multiple methods for reconstructing past water temperatures or salinity levels using elemental ratios (e.g., magnesium/calcium (Mg/Ca)) in sedimentary minerals, and using organic geochemistry. An important example of an organic geochemical technique used to measure temperature relies on the ratio of two plankton-derived compounds (alkenones) in marine sediments (Brassell et al., 1986). Ocean temperatures influence alkenone biosynthesis in a systematic manner, and thus the ratios of these compounds in sediments preserve past temperature trends (Müller et al., 1998; Prah and Wakeham, 1987).

Like qualitative paleoclimate data, quantitative estimates of past temperature and moisture levels have been important for computer-based studies of climate. Ocean temperature patterns inferred from fossil foraminifera assemblages (CLIMAP Project Members, 1981) were long used to provide the baseline ocean temperature data for computer simulations of Pleistocene conditions (e.g., COHMAP Members, 1988; Rind et al., 1986). Pollen-based inferences of terrestrial temperature and precipitation patterns have been used to test the accuracy of climate model output (e.g., Webb et al., 1993); syntheses of multiple quantitative approaches have been used to reconstruct temperature gradients during key intervals such as the Last Glacial Maximum (21 000 cal yr BP) and have also been the target of model experiments (e.g., COHMAP Members, 1988).

Present is the Key to the Past: Calibrating Proxies

When Agassiz (1840) postulated that ice ages had been part of Earth's history, he based his interpretation on the similarity between many geomorphic features found throughout Europe and the features found today near glaciers in the Alps. Likewise, many paleoclimatologists have used modern 'analogs' to inform their interpretation of proxy data. Tree-ring data have been interpreted through the establishment of calibration functions (regressions between historic conditions and historic growth patterns; Fritts, 1976), and similar calibrations have been done for many biotic and geochemical proxies (e.g., Müller et al., 1998; Smith, 1993). However, unlike tree-ring data, many calibrations rely on relationships (regressions) that link spatial (not temporal) patterns of climate with spatial patterns in biotic or geochemical data. The relationships then are applied to proxy data spanning centuries, millennia, or even the whole of the Quaternary, and thus, use information in space to gain information in time (e.g., Guiot, 1990).

Many quantitative techniques use equations, derived using modern climate-biotic assemblage datasets, to 'transfer' climate information onto biotic information (e.g., Bartlien and Whitlock, 1993; Imbrie and Kipp, 1971). Other techniques, however, explicitly rely on such an approach by statistically matching the composition of an assemblage of fossils to the composition of a modern biotic assemblage, thus inferring that the fossil assemblage represents the same set of conditions as the modern assemblage (e.g., Guiot, 1990). This 'modern analog technique' has often been applied to fossil assemblages of foraminifera in deep-ocean sediments (e.g., CLIMAP Project Members, 1981) and pollen in lake sediment (e.g., Bartlien and Whitlock, 1993; Guiot, 1990). Some modifications of the

approach include the generation of smoothed grids of possible analogs that span a wide range of climatic conditions by interpolation among modern samples (e.g., 'response surfaces' in Bartlien and Whitlock, 1993; Webb et al., 1993) and the use of neural networks, rather than explicit measurements of similarity, to find the best analogs (e.g., Peyron et al., 1998). More simply, growing-season and winter temperature inferences from beetle remains use the overlapping modern temperature preferences of the taxa found in a given sample (Atkinson et al., 1986).

Widely used geochemical proxies, such as isotope and alkenone records, also use relationships based on modern analogs to guide their interpretation (e.g., Müller et al., 1998), but many of these techniques rely on more fundamental relationships – established either from first principles or empirically (e.g., Prah and Wakeham, 1987; Urey, 1947). Similarly, temperature measurements from boreholes are quantitative in nature, but an understanding of physical processes must be applied to either establish the age of the measured temperature or the magnitude of signal attenuation over time. In this way, these geophysical measurements do not rely on 'analogs' but process-based understanding of the physics involved (Dahl-Jensen et al., 1998). Borehole temperatures have also been used to calibrate more detailed and chronologically controlled geochemical measurements of glacial ice (Cuffey and Clow, 1997). Thus, modern 'analogs' and their associated drawbacks can sometimes be avoided.

Quantitative Problems

A major problem for quantitative paleoclimate reconstruction arises from periods of the past that have conditions with no equivalent anywhere on Earth today. Modern analog methods fail if no analog exists. For example, fossil pollen records from the mid-continent of North America contain numerous samples from the late Pleistocene and early Holocene, which are compositionally unlike any modern sample of pollen; the assemblages appear to be the result of climatic conditions that had a more extreme difference in seasonal conditions (colder winters and warmer summers) than found anywhere today (Williams et al., 2001). Similarly, many biotic proxies may not find adequate analogs for Pleistocene conditions because atmospheric carbon dioxide levels were lower than those present during the Last Glacial Maximum and much of the Pleistocene. Higher plants and algae depend upon carbon dioxide for photosynthesis, and thus, ecosystems that developed under low carbon dioxide levels in the Pleistocene likely behaved differently to ecosystems today and conditions inferred from matching fossil and modern biotic assemblages may not be accurate (Cowling and Sykes, 1999).

Equation-based reconstructions can overcome the lack of modern analogs by extrapolation. Such equations may produce values beyond the range of modern data; however, the functions are not constrained under such circumstances and may be erroneous. Another approach to solving the problem involves modeling the processes involved in generating a proxy record, and thus, creating a paleoclimate reconstruction. The advantages of such an approach stem from the ability to understand the proxy mechanistically and account for complications which may not be tractable using statistical

reconstruction methods. For example, pollen-climate transfer equations can provide values of temperature and precipitation from Pleistocene pollen assemblages that lack modern analogs (e.g., Bartlién and Whitlock, 1993), but such reconstructions may be erroneous due to the influence of atmospheric carbon dioxide levels on vegetation dynamics (Cowling and Sykes, 1999). However, process-modeling of vegetation dynamics, including the influences of both climate and carbon dioxide, can help to constrain and improve the reconstructions (Guiot et al., 2000). An important caveat with such modeling approaches is the limited nature of models: processes may not all be incorporated, understood, or appropriately parameterized.

Processes Are the Key to Understanding: Process-Modeling as a Way for Reconstruction

Model-based reconstructions have played an important role in paleoclimate reconstruction. In particular, forward, process-based models have been used to make quantitative climate inferences from data that lack a method for statistical climate-proxy calibrations. Most prominently, estimates of past lake levels have been modeled to infer past precipitation rates (e.g., Kutzbach, 1980). In these cases, the hydrologic model is run in an attempt to simulate the observed changes in lake levels, and the range of conditions used as inputs into the model that produce satisfactory simulations can be inferred to represent the past conditions. Similarly, borehole temperature records rely on models of conduction and diffusion of heat over time to accurately interpret the raw down-hole data (e.g., Dahl-Jensen et al., 1998).

Synthesis

Paleoclimate reconstructions are most often made based on data from a single location. Interpretation of the climatic changes at a given study location, however, depends on knowledge about other places – perhaps even the rest of the world. Maps of paleoclimate data therefore are the ultimate reconstructions. They show empirically based representations of past climate gradients, which can be used to infer circulation patterns and other important dynamics (e.g., CLIMAP Project Members, 1981; COHMAP Members, 1988; Mann et al., 1998). Such inferences are limited if made from single proxy records alone, and like all paleoclimate reconstruction, can be made using qualitative or quantitative approaches. Qualitative approaches include either (1) inferring synoptic dynamics from climatic patterns (e.g., Shuman et al., 2002) or (2) finding a modern analog amid historic climate data that shows a pattern similar to the inferred past climate pattern (e.g., Mock and Brunelle-Daines, 1999). Quantitative approaches involve either (1) using statistical linkages between climatic values and synoptic climate dynamics (e.g., Webb and Bryson, 1972) or (2) comparing the data with climate model output (e.g., COHMAP Members, 1988).

Like the real-climate system, climate models produce fields of data that represent the spatial gradients of temperature, precipitation, pressure, and wind, as well as other variables (Bartlién and Hostetler, 2004). Comparisons of model output with maps of paleoclimate data thus provide important

insights, which benefit both the quest to improve climate models and to better understand past-climate dynamics. The comparisons reveal the ability of the model to accurately simulate conditions unlike those found today and show the types of dynamics that may explain past climate patterns (COHMAP Members, 1988). Therefore, in combination with climate model output, the paleoclimate record offers a rich source of insight into conditions unlike those experienced today.

Introduction

The Pliocene spans the interval of Earth history from ca. 5.3 to 1.8 Ma (including the Gelasian Stage of the Upper Pliocene, which is now considered the base of the Quaternary subera, beginning at 2.6 Ma). During the Pliocene, the Earth completed a transition from relatively warm climatic conditions, with little or no continental ice in the Northern Hemisphere, to more variable climatic conditions, with significant continental ice sheets in the Northern Hemisphere, and alternating glacial–interglacial cycles. The early Pliocene, from about 5.3 to 3.0 Ma, represents the last time in Earth's history when climates were generally warmer and more equable than modern climate. At the start of the late Pliocene (after 3.0 Ma), significant Northern Hemisphere ice sheets began to build-up, mid- and high-latitude areas cooled, and climate variability, as measured by $\delta^{18}\text{O}$ in deep-sea carbonate microfossils, increased. Distinct glacial–interglacial cycles developed between 2.9 and 2.7 Ma.

The high-latitude cooling and onset of Northern Hemisphere glaciation (NHG) that occurred in the late Pliocene represent the culmination of a trend that started 50 Ma in the early Eocene. [Figure 1](#) shows a composite 65 Ma $\delta^{18}\text{O}$ record measured in calcareous benthic foraminifers in deep-sea sediments. The $\delta^{18}\text{O}$ is a measure of the ratio of ^{16}O : ^{18}O in the shells of the Foraminifera, which is controlled primarily by the temperature of sea water and the $\delta^{18}\text{O}$ of sea water when the shell is formed. Lower temperatures and/or more global continental ice volume at the time of shell formation reduces the ^{16}O in the shell and results in a more positive $\delta^{18}\text{O}$. The global deep-sea $\delta^{18}\text{O}$ record for the last 50 Ma shows an overall increase continuing to the present day. From about 40 Ma to the present, much of the change in the $\delta^{18}\text{O}$ record reflects the buildup of polar ice volume and the related cooling of high latitudes ([Zachos et al., 2001](#)). Prior to 3 Ma, most of the ice buildup and variability was in Antarctica. The increase in $\delta^{18}\text{O}$ after 3 Ma is primarily related to the development and variability of Northern Hemisphere ice sheets. Most workers concur that the long-term trend seen in [Figure 1](#) is related to the overall decrease in atmosphere carbon dioxide (CO_2) concentrations ([Figure 2](#)) that led to an overall cooling of Earth.

Changes in the Earth's orbit alter the distribution of incoming solar radiation. The change in solar radiation causes long-term 10^4 – 10^6 oscillations in the Earth's climate. Orbital cycles include 19–23 ka cycles related to the precession of the Earth's rotational axis, a 41-ka cycle related to the tilt of the Earth's rotational axis (obliquity), and a 100-ka cycle related to the changes in the shape of the Earth's orbit around the Sun (eccentricity). The orbital forcing and the Earth's climate response to the forcing vary through time.

[Figure 3](#) shows a typical composite deep-sea bottom-water $\delta^{18}\text{O}$ record for the last 5 My. Most $\delta^{18}\text{O}$ values from 5 to 3 Ma

vary within a narrow range between 3.5 and 3.0‰. Isotopic values are generally similar or smaller than late Pleistocene interglacial values (shown by the dashed vertical line in [Figure 3](#)), which indicates that mid- and high-latitude conditions during the early Pliocene were usually as warm or warmer than late Pleistocene interglacial intervals. The amplitude of variability in the isotopic record is relatively small compared to the late Pliocene and Pleistocene, which indicates that variability in early Pliocene climate was subdued compared to later intervals. The isotope record contains 19–23-ka precession cycles. Early Pliocene climate was variable but in general warm intervals of the early Pliocene were as warm as or warmer than Pleistocene interglacial intervals whereas cool intervals were much warmer than Pleistocene glacial intervals.

After 3.0 Ma, excursions to increasingly more positive $\delta^{18}\text{O}$ are evident and distinct oscillations between smaller (interglacial) and larger (glacial) $\delta^{18}\text{O}$ become well defined. The increasingly positive $\delta^{18}\text{O}$ and the resulting higher amplitude cycles reflect the progressive intensification of NHG and development of glacial–interglacial oscillations that are typical of the late Pleistocene. Intervals when $\delta^{18}\text{O}$ were as small as late Pleistocene interglacial values became increasingly brief. Cooler and more glacial conditions became more prevalent toward the present. At about the same time that NHG intensified, 41 ka obliquity-related cycles became prominent in the isotope record. The change from precession-related variability to obliquity-related variability at about 3.0 Ma is seen in a variety of geologic records. The obliquity-related cycles continued to be prominent into the Pleistocene until about 1.0 Ma when 100-ka eccentricity cycles became prominent.

[Figure 3](#) also shows estimates of sea-surface temperature (SST) in the South Atlantic Ocean off the coast of South Africa as measured by the alkenone technique. From 4.8 to about 3.2 Ma, SST was warm and relatively stable. However, after 3.0 Ma the SST record shows a marked cooling trend and variability increased. The cooling trend in the SST record at this locality is a measure of the intensification of wind-driven upwelling associated with the Benguela Current ([deMenocal, 2004](#)). The SST record in [Figure 3](#) is typical of many climate records from the Pliocene in that most records from mid- and high latitudes indicate overall warmer conditions during the early Pliocene compared to modern and then show evidence of cooling and higher amplitude variability after about 3.0 Ma.

Warm Climates of the Early Pliocene

A survey of Pliocene climates, mostly covering the interval from about 4 to 2 Ma, has been done by the Pliocene Research, Interpretation, and Synoptic Mapping (PRISM) project ([Dowsett et al., 1999](#); [Poore and Sloan, 1996](#)). Evidence for warmer conditions during the early Pliocene was found in

many records from a variety of areas. For example, early Pliocene pollen records show that trees grew on the margin of the Arctic Ocean and on the continent of Antarctica (Thompson and Fleming, 1996). Warm water planktic microfossils were found in high latitudes of the North Atlantic and North Pacific

Figure 1 Composite global oxygen isotope record compiled from measurements of $\delta^{18}\text{O}$ in shells of deep-sea benthic foraminifers. The measurements were adjusted for vital effects. The red line represents an adjusted five-point running mean. Highly generalized occurrence of polar ice sheets is indicated by black bars. Black vertical bars show the occurrence of east and west Antarctic Ice Sheets and Northern Hemisphere ice sheets. Small and ephemeral ice sheets may have developed in the Northern Hemisphere as early as the late Miocene but permanent ice sheets did not develop until the middle of the Pliocene. Modified from Zachos J, Pagani M, Sloan L, Thomas E, and Billups K (2001) Trends, rhythms, and aberrations in global climate 65 Ma to present. *Science* 292: 686–693, reproduced with permission.

Oceans (Dowsett et al., 1996). The PRISM project integrated environmental records from 74 terrestrial localities and 77 marine localities into a synoptic compilation of representative conditions during a typical warm interval of a ‘time-slab’ from 3.15 to 2.85 Ma. Figure 4 shows a comparison of modern and the PRISM Pliocene global compilation of SST, sea ice, continental ice, and vegetation cover developed for climate modeling experiments. The compilation for the Pliocene is highly generalized and summarized on a 2° latitude by 2° longitude grid. The number of control points is especially limited in the Southern Hemisphere, and the details of the magnitude and timing of inferred Pliocene conditions can be questioned. However, the major differences indicated between the present day and early Pliocene are supported by multiple studies (Dowsett et al., 1999). SST in high and mid-latitudes were several degrees Celsius above modern. Evergreen vegetation was much more extensive in the Northern Hemisphere high latitudes during the early Pliocene, largely at the expense of more arid and cooler tundra and polar desert environments. Note the reduction in continental ice sheets (glaciers) compared to the present day and the absence of summer sea ice in the Arctic Ocean. The inferred reduction in continental ice sheets, as well as the elevation of geomorphic features such as Pliocene shorelines on continental margins, indicates that early Pliocene sea level was 20–30 m above modern sea level.

Mechanisms for Pliocene Warmth

Although climate records from a variety of areas indicate that climate during the early Pliocene was often warmer than modern climate, the explanation for the warmer climate is still a matter of debate. Mechanisms commonly mentioned as the forcing for warm early Pliocene climate include higher atmospheric concentrations of CO_2 , increased oceanic heat transport, and a permanent El Niño SST patterns in the equatorial Pacific Ocean.

Estimates based on carbon isotope records in marine deposits (Raymo et al., 1996) indicate that maximum global atmospheric CO_2 concentrations in the early Pliocene were around 425 ppm which is above the preindustrial (1850) atmospheric CO_2 level of 280 ppm but only slightly higher than the 2000 level of ~370 ppm. Estimates of Pliocene atmospheric CO_2 concentrations based on leaf stomatal frequency and size variation (Kurschner et al., 1996) suggest that

Figure 2 Estimates of atmospheric pCO_2 for the last 60 Ma. Reproduced from Zachos J, Pagani M, Sloan L, Thomas E, and Billups K (2001) Trends, rhythms, and aberrations in global climate 65 Ma to present. *Science* 292: 686–693, reproduced with permission. © 2001 AAAS.

Figure 3 Composite benthic foraminifer oxygen isotope record and estimated sea-surface temperature (SST) record derived from alkenone measurements in ODP Site 1048 off the coast of Namibia in the South Atlantic Ocean. The SST record shows that warm and relatively stable temperatures in the early Pliocene became progressively cooler and more variable after about 3.2 Ma. The cooling and higher variability reflect intensification of the wind-driven Benguela Current. The composite benthic foraminifer isotope record shows progressive cooling and build-up of global ice volume and during the late Pliocene into the Pleistocene. The dashed vertical line with the composite isotope record represents the expected value for Pleistocene interglacial intervals. Note that conditions as warm and with ice volume similar to Pleistocene interglacial times become increasingly brief from the late Pliocene to the Pleistocene. See text for discussion. Adapted from deMenocal PB (2004) African climate change and faunal evolution during the Pliocene–Pleistocene. *Earth and Planetary Science Letters* 220: 3–24. © 2004, reproduced with permission from Elsevier.

values varied between 280 and 370 ppm. The difference in atmospheric CO_2 levels between the Pliocene and today seems too small to account for the climate differences inferred from the geologic record (Crowley, 1996). In addition, warming due solely to increased atmospheric CO_2 should result in warming at all locations. In contrast, the available Pliocene observations indicate temperatures in most tropical areas were very similar to modern.

Increased oceanic heat transport is another mechanism that has been proposed to explain Pliocene warmth. Mapping of Pliocene SST estimates in the North Atlantic Ocean (Dowsett et al., 1992) and estimates of deep-ocean circulation based on carbon isotope gradients in deep-ocean basins indicate that thermohaline circulation (THC) was intensified during much of the early Pliocene. Increased THC would result in increased transport of warm low-latitude waters via the Gulf Stream into the North Atlantic Ocean and explain the increased SST inferred from microfossil assemblages preserved in deep-sea sediments (Figure 5). Increased transport of heat into the North Atlantic should result in cooler equatorial SST. However,

Figure 4 Comparison of generalized reconstruction of global environmental conditions for modern (top panel) and early Pliocene (bottom panel) warm intervals. Reconstruction is designed for use in modeling experiments and is done on a 2° latitude by 2° longitude grid. Top panel shows modern summer conditions. Bottom panel shows early Pliocene warm interval summer conditions. Land cover including glaciers and sea ice extent are color coded. SSTs are shown by isotherms in degrees centigrade. Open ocean areas are white. See text for discussion. Adapted from Dowsett HJ, Barron JA, Poore RZ, et al. (1999) Middle Pliocene paleoenvironmental reconstruction; PRISM2. *U.S. Geological Survey Open-File Report* 99-535, reproduced with permission.

available SST estimates from equatorial areas of the Atlantic indicate SST was similar to modern. It is possible that early Pliocene warming was due to some combination of slightly higher atmospheric CO_2 and increased THC.

Another proposed explanation for Pliocene warmth is that a permanent El Niño-like state existed in the early Pliocene. In the modern ocean, easterly winds in the equatorial Pacific essentially 'pile up' warm water in the western Pacific and cause upwelling of deeper cool waters to the surface in the eastern equatorial Pacific. The result is a west-to-east thermal gradient of about $3\text{--}7^\circ\text{C}$. During El Niño events, the easterly winds relax and the warm water in the western equatorial Pacific flows back to the east resulting in higher SST in the east and a reduction in the west-to-east thermal gradient. The change in equatorial surface water conditions alters atmospheric circulation patterns and affects climate conditions in a number of areas of the world through atmospheric teleconnections. The permanent El Niño theory for Pliocene warming argues that the modern temperature gradient across the equatorial Pacific Ocean was absent due to warmer SST in the

Figure 5 Map of North Atlantic Ocean showing difference in summer SST between early Pliocene warm interval and modern. Circled dots represent localities at which early Pliocene SST estimates were made. Contours represent estimated differences in SST in degrees Celsius. Early Pliocene SST in northeastern Atlantic was 5–6 °C higher in early Pliocene compared to today, suggesting increased heat transport by the Gulf Stream. Adapted from Dowsett HJ, Cronin TM, Poore RZ, Thompson RS, Whitley RC, and Wood AM (1992) Micropaleontological evidence for increased meridional heat transport in the North Atlantic Ocean during the Pliocene. *Science* 258: 1133–1135, reproduced with permission. © 2001 AAAS.

eastern equatorial Pacific, possibly because the Indonesian Seaway was more open, which would prevent pooling of water in the western equatorial Pacific. The more uniform temperature conditions from west to east would then foster increased meridional atmospheric heat transport (enhanced Hadley cell circulation) which provided the mechanism for increased warming in high and mid-latitudes (Molnar and Cane, 2002). Comparison of early Pliocene reconstructed climate estimates with climate anomalies experienced during El Niño events (Figure 6) show some similarities and provide support for the interpretation that modern El Niño teleconnections could explain early Pliocene conditions. The comparison must be evaluated with caution because the estimates of Pliocene conditions are derived from different times in the Pliocene and integrate different intervals of time. A recent SST reconstruction for the eastern equatorial Pacific (Wara et al., 2005) indicates that the temperature gradient across the equatorial Pacific was substantially reduced during the Pliocene compared to today, which is consistent with a permanent El Niño-like state (Figure 7). However, the reduced temperature gradient persisted until ~1.8 Ma, well after high-latitude cooling and build-up of continental ice sheets began in the late Pliocene. Thus, there is conflicting evidence for the correspondence of a reduced west-to-east thermal gradient in the equatorial Pacific and mid-to-high-latitude warming.

A number of modeling studies using PRISM boundary conditions have attempted to test the different mechanisms for explaining the warm Pliocene climates. A recent experiment using a fully coupled ocean–atmosphere model with PRISM boundary conditions and an atmospheric CO₂ level of 400 ppm indicated that lower albedo related to reduction of continental and sea ice may be the primary reason for increased warmth in mid- and high latitudes. The model

results also suggest that poleward heat transport was not an important factor in Pliocene warmth (Figure 8; Haywood and Valdes, 2004).

Intensification of NHG

The late Pliocene is marked by the development of significant Northern Hemisphere continental ice sheets, associated cooling of high latitudes, and the development of distinct glacial–interglacial cycles that are characteristic of the Pleistocene. The history of NHG is difficult to decipher from continental records because recurring glaciations often override and obscure the evidence for prior glacial advances. Examination of ice-rafted grains in deep-sea sediments adjacent to continents is often used to trace the evolution of continental ice sheets. When continental ice sheets reach coastlines, icebergs are calved and float out into the ocean. The subsequent melting of the icebergs releases rock fragments and other debris trapped in the ice and the debris drops to the sea floor. The amount, composition, and areal distribution of the ice-rafted debris (IRD) in marine sediments can then be used to infer the history of ice sheets and glaciers on the continents. Examination of sediment cores from the Iceland and Voring Plateaus reveals sporadic occurrences of IRD as far back as the Miocene. However, the ice-rafted material is minor and it is not clear if it is derived from sea ice or icebergs. Figure 9 shows the abundance of IRD in a deep-sea core recovered from Ocean Drilling Site 907 in the Norwegian–Greenland Sea adjacent to southwestern Greenland. The occurrence of IRD in the core at about 3.3 Ma provides evidence that enough continental ice had built up at that time in southern Greenland to release icebergs out into Norwegian–Greenland Sea. After 3.0 Ma, the consistent presence of IRD and recurring peaks in abundance represent the beginning of permanent ice caps that periodically varied in size (Jansen et al., 2000).

The character and age of rocks on continents is variable. Analyses of the types of ice-rafted rock fragments and mineral grains contained in sediment cores adjacent to continental areas can be used to identify the source area of grains and thus provide information on the time of formation and geographic extent of past glaciers. A summary of the build-up of continental ice sheets in the Northern Hemisphere is shown in Figure 10. The formation of small ice sheets began during the early Pliocene in southern Greenland and then spread to northern Greenland by about 3.0 Ma. Between 2.8 and 2.5 Ma ice sheets developed in Eurasia, Alaska, and North America. As noted in Figure 10, the development of Northern Hemisphere continental ice sheets was a phased process. As much as 200 ka may have elapsed between the establishment of major ice sheets in Alaska and Eurasia and the establishment of ice sheets in North America. Glacial–interglacial oscillations become distinct in the deep-sea oxygen isotope records between 2.9 and 2.7 Ma coincident with the continued build-up of the Northern Hemisphere continental ice sheets. At the same time that continental ice sheets were building up in the Northern Hemisphere, the Antarctic Ice Sheet was also expanding. Details of the late Pliocene history of the Antarctic Ice Sheet are not well known.

Figure 6 Map comparing typical El Niño precipitation and temperature anomalies in winter (December–February) and summer (June–August) with selected early Pliocene climate estimates. Colored shapes designate areas of El Niño anomalies. Pliocene climate estimates are noted in black lettering. Modern El Niño anomalies are from the National Weather Service Climate Prediction Center. Cause of NHG

Several tectonic events that altered oceanic or perhaps atmospheric circulation have been proposed to explain the intensification of NHG in the late Pliocene. Some of the possible events include the closing of the Isthmus of Panama, the closure of the Indonesian seaway, the uplift of the Tibetan Plateau, the deepening of the Bering Straits, and the deepening of the Greenland–Scotland Ridge ([Cane and Molnar, 2001](#); [Maslin et al., 1998](#)). When examined closely, none of these events appears to provide a complete explanation for the intensification of NHG. For example, the closure of the Isthmus

of Panama caused an increase in salinity of the Caribbean and presumably increased the strength of the Gulf Stream. It has been suggested that increased transport of warm, salty water to the North Atlantic by an enhanced Gulf Stream would have provided a source of moisture to grow ice sheets on the adjacent continents and also increase formation of North Atlantic deep water (NADW). However, the closure of the Isthmus of Panama was not a discrete event; it occurred gradually and over a long period, from about 4.5 to 2.0 Ma. In addition, carbon isotope records from North Atlantic deep-sea cores indicate NADW formation decreased from 3.5 to 2.0 Ma.

Figure 7 Estimated temperature gradient between western and eastern equatorial Pacific Ocean for last 5 Ma. Note that the gradient was greatly reduced from 1.8 to 5.0 Ma compared to gradient of 4–7 °C after 1.8 Ma. See text for discussion. A reduction in atmospheric CO₂ concentration has been proposed as the cause for NHG. However, there is no clear evidence for a significant lowering of atmospheric CO₂ levels coincident with the intensification of NHG. In addition, a cooling related to lowered atmospheric CO₂ should be recorded in low latitudes but there is no evidence that tropical climates cooled at the beginning of the late Pliocene.

Variations in solar insolation reaching Earth's surface due to changes in Earth's orbit (orbital forcing) have also been proposed as an important cause for the intensification of NHG. In theory, ice sheets should form when summer temperatures are low enough to allow winter frozen precipitation (snow and ice) to survive the summer and thus begin a positive cooling feedback through increased surface albedo. The initial build-up of ice sheets in Alaska, Eurasia, and northeastern North America between 2.75 and 2.55 Ma (**Figure 10**) occurred when calculations show Northern Hemisphere summer insolation at 65°N reached minimum values (Maslin et al., 1998; **Figure 6**). However, similar or even lower summer

Figure 9 Abundance of ice-rafted debris (IRD) in sediments from ODP Site 907 just east of southern Greenland. Note consistent occurrence of significant amounts of IRD after 3.0 Ma. insolation values occur periodically earlier in the Pliocene, so summer insolation variability is not the sole cause of NHG.

Stratification and the resulting late summer warming of North Pacific surface waters at about 2.7 Ma have also been linked with the intensification of NHG. In addition to cooling, a source of moisture must be available to permit sufficient snow to grow ice sheets. In the modern ocean there is a large seasonal variation in SST in the sub-Arctic Northwest Pacific due to the formation of a seasonal thermocline. During

Figure 10 Map and graph showing location and timing of build-up of Northern Hemisphere continental ice sheets large enough to release icebergs into the ocean. Repeated glacial build-up occurred in Iceland during the Pliocene but the timing of the first sustained ice sheet is not well established. Open circles with three digit numbers represent Ocean Drilling Program cores used to establish ice sheet history. Arrows and fronts outline possible atmospheric circulation in preglacial Pliocene. Adapted from Maslin MA, Li XS, Loutre MF, and Berger A (1998) The contribution of orbital forcing to the progressive intensification of Northern Hemisphere glaciation. *Quaternary Science Reviews* 17: 411–426. © 1998, reproduced with permission from Elsevier.

winter, when no thermocline is present, surface waters are well mixed with subsurface water. SST is about 1 °C (February) and surface waters are rich in nutrients mixed from below. In summer, when a thermocline is present, surface waters are isolated from cool subsurface waters and late summer SST (September) is 12 °C. Estimates of North Pacific SST derived from analyses of alkenones, which likely reflect late summer SST (Haug et al., 2005) indicated SST increased by about 7 °C near 2.7 Ma. The increase in temperature is considered to reflect the development of a seasonal thermocline in the North Pacific, which would allow the large seasonal range in SST observed in the modern ocean. The presence of warm surface waters in the North Pacific in fall would enhance transport of moisture onto the adjacent cooler continents and increase snowfall and thus promote build-up of continental ice sheets. Haug et al. (2005) proposed that prior to the development of a seasonal thermocline at

2.7 Ma, surface waters would have remained cool during the seasonal cycle due to mixing with cooler subsurface waters. One problem with this theory is that alkenone SST estimates indicate that sub-Arctic North Pacific SSTs were nearly as warm at 2.9 and 3.0 Ma as they were at 2.7 Ma. In addition, the assumption that seasonal signals can be extracted from Pliocene proxy records needs additional testing.

Comparison of detailed climate proxy records from tropical to subpolar areas in the Northern Hemisphere indicates no clear pattern of cooling in the late Pliocene across latitudes or regions. Ravelo et al. (2004) concluded that regionally specific processes caused climatic cooling at different times and that the termination of the early to mid-Pliocene warm interval was not forced by a single event whose effects were propagated globally. Thus, as of this writing, no clear single cause has been identified as the ‘triggering event’ leading to the NHG.

Figure 11 Summary of Hominid Evolution in Africa compared with evolution of Pliocene and Pleistocene climate as measured by soil carbon isotope values in East Africa and composite benthic foraminifer deep-sea isotope record. Note increase in Hominid speciation coincides with expansion of grasslands, initiation of NHG, and change to 41 ka cycles near 3.0 Ma. Adapted from deMenocal PB (2004) African climate change and faunal evolution during the Pliocene–Pleistocene. *Earth and Planetary Science Letters* 220: 3–24. © 2004, reproduced with permission from Elsevier.

Links Between NHG and Human Evolution

Records of African climate and climate variability derived from studies of deep-sea cores and continental records generally show a change from wetter and warmer conditions in the early Pliocene to cooler and drier conditions with higher variability in the late Pliocene. Pollen records from a variety of sites indicate that woodland areas were replaced by more open savannah grasslands (deMenocal, 2004; Thompson and Fleming, 1996). After about 3.0 Ma, variability in African wet-dry cycles as monitored by the abundance of African-source dust in deep-sea cores indicates that African climate cycles correspond closely with variation in high-latitude continental ice volume cycles. In general, glacial climates result in cooler and more arid conditions. Changes in the African mammal fauna including hominids broadly coincides with the change in climate and landscape that marks the development and intensification of NHG (Figure 11). Analyses of bovids (antelope group) and micromammal assemblages (e.g., rodents) indicate that arid-adapted taxa were more prevalent after 3.0 Ma. The diversification of hominids coincides with the change in pace of climate variability and the expansion of grasslands. It is not clear if the change in timing and magnitude of climate variability or the change to more arid conditions or some combination of both was the primary cause of the change in mammal faunas

(deMenocal, 2004). Although the details are still being debated, the available evidence indicates that the evolution of hominids was linked to the change in climate associated with the onset and intensification of NHG during the late Pliocene.

Introduction

Severe drought is a recurring natural hazard that has prominent economic and agricultural impacts on society. Many societal planning schemes are based on the modern records of interannual and decadal drought variability (Stockton, 1990). The modern record of drought is restricted temporally and geographically, depending on the availability of systematic instrumental weather records. For example, our observed record of drought for North America covers mostly the last 100 years, whereas such modern records cover substantially longer periods for Europe and East Asia. Some scholars have conducted research on the observed record of severe drought, noting periodic cycles of aridity for some regions, such as the 22-year drought cycle in interior North America. These drought cycles have been somewhat disputed because of the temporal limitation of coverage by the modern instrumental record. Paleoclimatic reconstructions of drought have been conducted from a variety of different proxy data, with some reconstructions translating proxy terms into drought indices (e.g., Stable et al., 1998), and others providing more relative or presence/absence information on drought conditions (e.g., Mason et al., 1994). These paleoclimatic reconstructions provide a longer perspective of drought variability for a region, enabling a clearer analysis of the forcing mechanisms of severe drought, improving probabilistic models of future drought prediction, and contributing to a more comprehensive analysis of drought impacts on past societies. This article presents an overview of the way some of the important types of terrestrial paleoclimatic data are utilized in a drought context at different temporal scales within the Holocene, and the way they are assessed in conjunction with potential forcing mechanisms of past climate, emphasizing examples from North America. The article emphasizes temporal variability at annual to decadal timescales, as this variability is the common element that directly links past drought to the modern instrumental record (Overpeck and Webb, 2000). Data for the paleoclimatic reconstructions used in this article were taken from the NOAA Paleoclimatology website at <http://www.ncdc.noaa.gov>.

Paleoclimatic Proxies of Past Drought

This section does not describe the extreme details of all the different types of proxy data or the numerous complexities of drought signals from different proxy data types. For further information, refer to Bradley (1999) and specific references cited in it related to particular proxy data and dating techniques.

Historical Records

Historical (noninstrumental) evidence of drought consists of accurately dated documentary records such as diaries,

newspapers, and chronicles (Baron, 1989). Documentary records provide the highest resolution of all the paleoclimatic proxy data types, enabling detailed reconstructions of daily weather events that may lead up to severe drought. Some documentary evidence, such as annals, letters, and almanacs, possess less temporal resolution. They are reflective of monthly, seasonal, or annual conditions. However, these lines of evidence still provide some general information on extreme drought years (e.g., Therrell et al., 2004). The documentary materials, however, cannot be taken at face value, as poor data quality from unreliable records makes some materials inappropriate for climate reconstruction. Written descriptions of drought may also reflect individual biases based on diarists' personal background and particular motivation for writing. Thus, a thorough knowledge of the documentary materials is essential, and copious daily records enable more accurate quantitative assessments of past drought, such as by analyzing the number of rain days. Content analysis also provides a means of quantifying documentary information into drought and climate terminology (Baron, 1989).

An example of a composite of warm-season rain days has been compiled for Charleston, South Carolina, from numerous documentary records dating back to the early nineteenth century (Figure 1). A distinctive persistent period of relatively lower number of rain days is evident for the mid-nineteenth century, during a time frame when documentary evidence is clearly plentiful. Additional descriptions of verbal evidence from plantation diaries in South Carolina during this decrease of precipitation frequency reveal that farmers continuously wrote about drought, but note that precipitation frequency can differ from precipitation magnitude, so it should not be interpreted as being necessarily the worst period of drought severity in the entire record.

Tree Rings

Trees that exhibit seasonal variations in light, thin-walled earlywood and dark, thick-walled latewood cells in tree growth have annual rings, thus making tree rings an important proxy source for analyzing climatic change at shorter timescales within the last few thousand years. Tree rings, particularly at sites from lowland moisture-sensitive areas, have been used extensively for reconstructing past precipitation and drought in North America during the last several hundred years, with some sites reconstructing drought history over the last millennium (e.g., Hughes and Funkhouser, 1998). Researchers have examined the widths of tree rings as well as tree-ring densities in relation to climate (Schweingruber, 1987). Some tree-ring reconstructions of past drought focus on site-specific areas at about the size of a drainage basin, and some reconstructions apply multivariate statistical methods on a network of tree-ring sites at regional and national scales (Cook and Krusic, 2004). Reconstructions also vary in their temporal resolution, as some

Figure 1 Annual frequencies of June–September rain days in Charleston, South Carolina, USA from 1823 to 2005, as reconstructed from documentary evidence.

studies may be reflective of drought of a particular seasonality, and some reconstructions may generally reflect annual or longer conditions of drought. For example, Woodhouse et al. (2002) reconstructed May–July Palmer Drought Severity Indices (PDSI) back to the 1500s for Eastern Colorado, USA. Interpretation of the PDSI equates decreased negative values as corresponding to increased severity of drought. This reconstruction indicates severe droughts centered around the 1950s, 1930s, 1840s, and a series of more frequent severe droughts during the 1570–1750 period. This reconstruction is typical of those that do not clearly illustrate distinctive specific drought cycles throughout the entire record. The nature of more persistent and frequent droughts in the past prior to the modern instrumental record reveals the importance of obtaining a longer temporal perspective on drought. Cook and Krusic (2004) utilized a network of 835 tree rings to reconstruct annual spatial patterns back several centuries for North America. Their example for 1820 indicates that severe drought is clearly evident over the southern Great Plains and much of the southwestern United States (Figure 2), which corresponds to the Long expedition's travels across the region that created the notion of the Great American Desert (Lawson and Stockton, 1981).

Lake Records

A variety of proxy evidence concerning the paleolimnology of lakes can be applied to detect decadal drought variations as well as those that prevailed up to centennial timescales for the late Quaternary period (Street-Perrott and Harrison, 1985). The geochemistry from lake cores also provides evidence since chemical and isotopic components change in response to salinity changes which are related to past drought. Radiocarbon dating provides most of the dating control for the last 20 ka. However, varves may occasionally be found in some lakes, providing annual dating, while trace elements (e.g., sodium and potassium), pollen, and diatoms can also be examined to obtain paleoclimatic information (Bradbury et al., 1993). Much research has emphasized the reconstruction of past lake levels, including those with closed basins (e.g., Harrison et al., 1996 and Shuman et al., 2002). At larger regional and continental spatial scales, broad synchronous decreases in lake levels from a high number of sites reflect prolonged severe drought. Generally, lake-level fluctuations are due to combined effects of precipitation, evaporation, lake area, runoff, discharge, groundwater, and tectonics. Lower lake levels may generally reflect decreased effective

moisture, which includes decreased precipitation and/or increased evaporation.

Considerable attention has been focused on the reconstruction of spatial patterns of drought in the mid-Holocene, around 6 ka, for central and western North America. Lake levels were interpreted as low relatively to modern day, enabling qualitative interpretations that widespread aridity existed over the Pacific Northwest, extending into the western interior of the Great Basin. This widespread aridity corresponds to the Altithermal, which has been used for a number of decades to describe persistent mid-Holocene drought over parts of North America (Harrison et al., 2003; Mock and Brunelle-Daines, 1999). The causes of widespread drought are largely related to synoptic-scale atmospheric circulation that includes a stronger Pacific subtropical high over the eastern Pacific Ocean, and a strong subtropical ridge over the mid-continent.

Fossil Pollen

The accumulation of fossil pollen over time at a site as reflected in cores of peat bogs and lake muds, aided by radiocarbon dating, enables the reconstruction of vegetation history and related paleoclimatic interpretation, including the study of drought at millennial timescales. Care must be taken when making paleoclimatic interpretations from pollen, because of problems with pollen dispersal and production rates and lake basin characteristics. Vegetation may always not always be in equilibrium with climatic change (Davis and Shaw, 2001), with factors including substrate, migration lag, and disturbances such as fire playing a more dominant role in vegetation change. However, widespread drought and vegetation are generally in equilibrium with one another on late Quaternary timescales within approximately 1.5-ka intervals at the continental scale (Shuman et al., 2002). Evidence of past drought from pollen data can be conducted through qualitative methods such as using an indicator-species approach, presuming that particular taxa respond to the primary climatic changes that occurred in the past. A multiproxy map of paleoclimate for the mid-Holocene shows that pollen data can supplement lake-level data in relative terms. Results for 6 ka from pollen assemblages also support widespread aridity over the Pacific Northwest US and into the western interior (Mock and Brunelle-Daines, 1999), and the pollen data have been taken from more sites than have the lake-level data for the western United States. Quantitative approaches, using modern vegetation/climate relationships and multivariate statistical methods, have also been used to reconstruct the past.

Diatoms

Diatom records can reconstruct paleoclimatic conditions at decadal to millennial timescales within the late Pleistocene (e.g., Laird et al., 2003), given precise dating (e.g., varves, ^{210}Pb dating, ^{14}C dating). Since different species of diatoms thrive in different paleolimnological conditions, some provide specific drought information, based on such variables as salinity, nutrient availability, and habitat availability. Also, as with pollen, statistical methods can be applied to diatom data to quantitatively reconstruct paleoclimate (Moser et al., 1996). An example of a reconstruction of salinity from Moon Lake in the northern Great Plains illustrates that decadal to

Figure 2 Reconstructed Palmer Drought Severity Indices (PDSI) map for 1820 from tree rings (Cook and Krusic, 2004).

centennial variations of drought were more frequent prior to 1.2 ka (Laird et al., 1996). One of the most severe drought intervals was centered around the Medieval Warm Period from AD 800 to 1200. However, this dry episode may reflect regional changes in synoptic-scale atmospheric circulation or perhaps a difference in seasonal precipitation regimes, as similar diatom reconstructions for other sites in the northern Great Plains differ somewhat in their reconstruction of drought history (Laird et al., 2003). Fossil diatom assemblages from Moon Lake extend back through the Holocene. These data reveal that persistent drought was prevalent from around 7.3 to 4.4 ka, corresponding to the widespread mid-Holocene aridity reflected by other drought proxies (e.g., pollen and lake levels) in North America.

Eolian Records

The stratigraphy of eolian deposits, such as sands, may indicate periods of past aridity and dune reactivation. One example of this comes from aridity in the mid-continent of North America around 6 ka (e.g., Muhs and Zarate, 2001 and Wolfe et al., 2002). Paleowind directions may be inferred from features such as sand dunes, yardangs, and wind furrows. However, nonclimatic factors such as faulting, and site-specific variations in sediment thickness and texture need to be considered. Furthermore, for some locations, single extreme windstorms of a few days' duration may contribute much of the eolian

deposition, as opposed to sustained background deposition over centuries.

Climatic Forcing Mechanisms of Past Drought

General circulation models (GCMs) simulate the geographical distribution of climatic variables at hemispheric and global scales. They are based on fundamental laws that include the ideal gas law, conservation of energy, conservation of mass, and Newton's second law of motion. These fundamental laws explain, theoretically, how the physical processes occur between, within, and among the different components of the climate system. The physical processes are represented by layers of horizontal grids, with the number of layers as well as horizontal resolution varying between different GCMs. Given an appropriate set of boundary conditions of a past interval of interest to a researcher, GCMs can simulate the three-dimensional character of particular episodes of severe drought. Climate modeling of drought for episodes in the modern climate record of North America has received significant attention. For example, Schubert et al. (2004) illustrated that anomalous negative sea-surface temperatures in the tropical Pacific combined with anomalous positive sea-surface temperatures in the tropical Atlantic weaken the low-level jetstream in the southern Great Plains. This situation corresponds with patterns of severe drought over central North America, resembling the 1930s Dust Bowl.

Seager et al. (2005) also modeled the response of low-frequency drought episodes over North America from tropical forcing, not only illustrating the importance of sea-surface temperature forcing but also acknowledging the additional importance of land–atmosphere interactions. In addition, they described the importance of cool ‘La Niña-like’ sea-surface temperatures in the eastern tropical Pacific Ocean on creating the persistence of severe drought. Herweijer et al. (2006) performed modeling simulations of the following North American droughts: 1856–65, 1870–77, and 1890–96, as well as two Medieval drought episodes in the western United States. They further illustrate the importance of a colder tropical Pacific Ocean in creating severe drought. These model simulations generally compare quite well with drought networks of proxy data. Hunt and Elliott (2002) attempted to simulate Mexican megadroughts (persistent droughts of more than a decade in duration), suggesting the importance of El Niño events and various stochastic processes, but their work implied that a more specific understanding of the potential mechanisms is needed to improve the modeling of a megadrought.

Numerous model simulations exist for 6 ka because this time frame was the particular focus of the Paleoclimate Modeling Intercomparison Project (Joussaume et al., 1999). Practically, all of the models agree on the positions and anomalies of large-scale synoptic features over North America (e.g., a stronger Pacific subtropical high during most of the summer). However, some subtle differences in the specific positions of synoptic features, such as the upper-level subtropical ridge over the southern United States, can play important roles on the geographical distribution of monsoonal activity and areal extent of aridity (e.g., Mock and Brunelle-Daines, 1999). The climatic forcing mechanisms at 6 ka are also related to orbital parameters of an increased tilt and changes in precession, plus important ocean feedbacks were also prominent as well (Harrison et al., 2003), and different seasonal precipitation regimes are characteristic of the climate over western and central North America (Mock, 1996). Therefore, one cannot limit the causes of widespread drought in the mid-Holocene to just a few specific parameters.

Impacts of Paleodrought on Past Societies

Although the impacts of drought on earlier societies cannot be assessed in the same ways as can be done in the modern era, some useful lessons can nonetheless be learned from an understanding of premodern drought impacts. The roles of social, economic, and political factors have been studied extensively, using case studies of societal collapses and political unrest, but the role that the climate, including drought, has played in human societies has not received due attention in many cases. A longer temporal perspective of drought and societal impacts can be invaluable in assessing how societies adapt to drought in longer time frames as they also involve technological and ideological changes through time (deMenocal, 2001). Some scholars have long been interested in the role of drought in societal collapses and disappearances, including the case study of the Akkadian collapse in the Near East around 4.2 ka (Cullen et al., 2000). Establishing clear linkages between drought and the decline of past societies requires high-quality

dating control on both the drought events of interest and on evidence of the impacts (e.g., archaeology). For example, some societies may be quite sensitive to single or perhaps a series of extreme drought years, and this requires dating no less precise than annual resolution. Some societies may be quite responsive to decadal drought variations, which can be dated using calibrated radiocarbon.

An 800-year tree-ring record of baldcypress trees was used to reconstruct July Palmer Hydrological Drought Indices from the Tidewater region of coastal Virginia and North Carolina. This record reveals two extremely severe droughts that coincide with prominent historical events. A persistent and severe 7-year drought occurred from 1606 to 1612, which contributed immensely to crop failures and poor water quality at the Jamestown Colony – this eventually contributed to the high mortality rate (Blanton, 2000; Stahle et al., 1998). A shorter but more severe drought is also evident for 1587–89, which coincided with the disappearance of the Lost Colony at Roanoke Island. Although nonclimatic factors clearly played important roles in both of these historical events, the strong negative drought anomalies cannot be ignored as an important factor, for even modern society would face extreme hardships in such extreme drought conditions. Overall, a prolonged drought of several decades in the late sixteenth century is evident in many tree-ring records from much of North America, corresponding to what has been termed the big ‘megadrought’ (Stahle et al., 2000). A number of prominent drought impacts on society have been linked to this megadrought, including epidemics of cocoliztli (indigenous hemorrhagic fevers) in the mid-1500s that decimated around 80% of the native population in Mexico (Acuna-Soto et al., 2002).

Widespread severe drought also occurred around the late 1200s over many parts of North America. Severe drought occurred in the southwestern United States (Cook et al., 2004), which may relate to the Anasazi collapse, and over the middle of the United States, which may explain the disappearance of the Mill Creek Indians in Iowa (Bryson and Murray, 1977). Overall, the western United States experienced more frequent and severe droughts from AD 900 to 1300 as compared to the normal variability of the last century (Cook et al., 2004). Another prominent and extremely severe drought that likely had a dramatic impact on society, as reflected in oxygen isotopes and gypsum from lake cores and sediment records from the Cariaco Basin in the Caribbean Sea, occurred mostly around AD 800–900 in the Yucatan Peninsula, causing the classic collapse of the Mayan civilization (e.g., Curtis et al., 1996; Haug et al., 2003).

Bowden et al. (1981) described two hypotheses that deal with the changing characteristics of climatic impacts on society through time – lessening and catastrophe – both dealing largely with drought hazard. The lessening hypothesis suggests that societies are better able to adapt to minor climatic stress through time given improved technology, increased social organization, and mitigation. The catastrophe hypothesis suggests that societies become more vulnerable to major climatic stress as time progresses due to their increased vulnerability, which is related to increased reliance on technology and social organization. Bowden et al. (1981) tested these hypotheses on three regions using available climatic and population data: India, the US Great Plains, and the African Sahel. They found

some clear indications of lessening, but results are less clear for catastrophe given the limitations on data quality and record length (including paleoclimatic data). Riebsame (1991) continued to examine these two hypotheses for the US Great Plains in extrapolating into a world of future global warming, addressing societal concerns for the catastrophic aspects. This framework of the hypotheses for assessing future climate impacts may prove quite valuable for some regions if they possess well-dated and interpreted paleodrought and archaeological evidence.

Conclusions

Reconstructions of past droughts prior to the era of systematic modern instrumental records provide a valuable longer perspective of drought that allows a fuller understanding of the recurrence of such extreme events and their duration and magnitude. The emphasis in this article has been on examples from North America, but such approaches for understanding past drought have also been employed for other areas of the world where drought is a prominent hazard (e.g., Overpeck and Webb, 2000; Touchan et al., 2003). These aspects of paleodrought at different temporal and spatial scales are critical for societal planning schemes such as dam and water regulation (Meko et al., 1995). Accurate reconstructions of paleodroughts can also aid in the study of famous historical events and the disappearance or disruption of past societies. Establishment of clear relationships between past drought and societal responses requires multidisciplinary approaches from the scientific, social science, and historical fields.

The Quaternary has seen a succession of glacial–interglacial cycles lasting from 20 to more than 100 ka driven primarily by Milankovitch forcing (oscillations of the Earth's orbit around the Sun). However, more rapid, large-amplitude climatic changes are now recognized in all high temporal resolution paleoclimate records. The terms Dansgaard–Oeschger (DO) cycles and Heinrich events (HEs) designate specific events linked to climatic changes, which occurred during glacial periods on timescales of decades to centuries. DO cycles are designated in honor of Willy Dansgaard and Hans Oeschger, renowned geochemists and pioneers of ice core studies (Dansgaard et al., 1993). They described the succession of interstadials (warm episodes) and stadials (cold episodes) recorded as oscillations in the oxygen isotopic ratios in Greenland ice cores (Johnsen et al., 1997; North Greenland Ice Core Project, 2004; Figure 1).

Twenty-five such 'events' are described for the period from 120 to 10 ka BP. Each DO corresponds to (1) a relatively gradual cooling of $\sim 5\text{--}10\text{ }^{\circ}\text{C}$ (at the altitude of the Greenland ice sheet) that lasted $\sim 600\text{--}2000$ years; (2) a subsequent, more rapid decline of $\sim 5\text{--}10\text{ }^{\circ}\text{C}$ into peak stadial conditions, lasting another 300–700 years; and (3) a very abrupt return ($\sim 3\text{--}5\text{ }^{\circ}\text{C}$ warming per century) to interstadial conditions. HEs are named after their discoverer Harmut Heinrich, who in 1988 observed a succession of sand layers in glacial sections of sediment cores taken from the top of a deep seamount from the northeast Atlantic, which he rightly attributed to a succession of periods of large-scale iceberg melting and sedimentation of ice-rafted detritus (IRD). Wally Broecker, who coined the terms in 1992, was the first to recognize the implications of Heinrich's discovery, including the probable climatic links between large iceberg surges, meltwater input to the North Atlantic, interruption of the thermohaline circulation, and high-latitude cooling. Gerard Bond and coauthors (1992, 1993) published the first detailed descriptions of these events (Figure 2) and suggested the climatic links between DO cycles and HEs. They have shown in particular that for four of the five HEs recorded in North Atlantic sediments during the last glacial period between 70 and 20 ka BP, peak IRD deposition corresponds to the coldest phase of a DO stadial and is directly followed by a pronounced warm interstadial. The last typical Heinrich event, HE1, occurred during the early phase of the last deglaciation (or 'termination'); this is a period for which precise correlation of marine IRD records with the Greenland ice core records is difficult due to the occurrence of several large-amplitude climatic oscillations within a few millennia (including the Oldest and Older Dryas). However, as for other HEs, HE1 was followed by a major warming, which in this case constituted most of the deglacial temperature change in the North Atlantic region during the last termination. The Younger

Dryas, which interrupted the last deglaciation between 12.5 and 11 ka BP (calendar years), is now generally considered as the last Heinrich event (HE0). Since the early 1990s, it has become increasingly apparent that the impact of these climate events has not been restricted to the North Atlantic region, and that evidence for similar perturbations exists from throughout the world – in the surface and deep ocean, on the continents (low and high latitudes), and in the polar ice sheets of both hemispheres (Sarnthein et al., 2002).

The study of millennial climate events and their global teleconnections is complicated by the difficulty involved in placing them in a sufficiently precise chronology. Uncertainty in the ^{14}C chronology readily exceeds a few hundred years for ages older than ~ 15 ka BP. Calibration of radiocarbon ages is complicated by the nonlinear relationship between calendar age and ^{14}C dates. Dating of marine records involves the added uncertainty of poorly constrained 'reservoir age' variability because marine carbon is not exchanged sufficiently rapidly with the atmosphere to result in 'zero-age' surface water. None of the classical stratigraphic tools are applicable for distant correlations because most of them depend on climate-related proxies (e.g., stable oxygen isotopes in ice and Foraminifera or the distribution of stenotopic species) that will not necessarily have changed in synchrony across different climatic zones or (in the case of global geomagnetic or glacio-eustatic methods) are simply not sufficiently precise relative to the duration of the events being studied. Nevertheless, correlations between proxies at the regional scale are sufficiently precise and allow the detailed study of local interactions during rapid climate changes between ice sheets, ocean, and continental surfaces.

The following sections briefly present some of the proposed origins and global consequences of past submillennial-scale climate change, as inferred from their impacts on various paleoclimate proxies. In this presentation, which is based on the state of knowledge as of mid-2005, and to a certain extent on our own scientific bias, we simplify the current understanding of the climate system a great deal. Therefore, we cannot pretend that this summary will represent a consensus, which in many cases does not yet exist.

High-Latitude Signals

The various Greenland ice core records are strikingly similar, exhibiting the same series of characteristic DO climate events (Figure 1). Each DO cycle represented in the Greenland temperature record has been linked with a large-scale reorganization of the atmospheric circulation around the Northern ice sheets. The approximately 'sawtooth' waveform described by

Figure 1 Ice $\delta^{18}\text{O}$ records along central Greenland drillings: the GRIP and North Grip (NGRIP) records. Redrawn from North Greenland Ice Core Project (2004) High-resolution record of Northern Hemisphere climate extending into the last interglacial period. *Nature* 431: 147–151; with the original GRIP timescale of Johnsen et al. (1997) and numbered DO.

Figure 2 Records of the rapid climatic variability around the northern Atlantic Ocean. (a) The GRIP ice $\delta^{18}\text{O}$ record with numbered interstade cycles. (c) Same for DSDP site 609 (49°53' N, 24°14' W). (d) *N. pachyderma* $\delta^{18}\text{O}$ (note inverted scale). The negative $\delta^{18}\text{O}$ anomaly linked with cold events tracks the surging iceberg meltwater during Heinrich events H1–H6. Redrawn from Bond G, Broecker W, Johnsen S, et al. (1993) Correlations between climate records from North Atlantic sediments and Greenland ice. *Nature* 365: 143–147.

the Greenland ice core isotopic records is also present in Atlantic records of sea surface temperature at $\sim 45^\circ \text{N}$ (Figures 1, 2, and 6), suggesting that DO cycles and HEs were linked to latitudinal oscillations of the polar front and the associated wind-driven circulation.

However, ocean sediment records may present different signatures depending on their location and proximity to the ice sheets. Much knowledge has been acquired by the study of sediment cores sampled from throughout the world under the IMAGES program (International Marine Past Global Changes Study) with the giant corer aboard the research vessel Marion Dufresne, and with the research vessel Hudson in the Labrador Sea and the Ocean Drilling Program in the North Atlantic.

Exceptional records obtained in the Nordic seas show that a large fraction of the Greenland and Norwegian seas were free of sea ice, at least in summer, during warm interstadials. Sea ice probably extended much further during stadials. Magnetite particles eroded by weathering of old volcanic margins were actively transported during each interstadial to the northern Atlantic, thus indicating significant deep-water production and transport at these times. The magnetic susceptibility records in

key regions of the North Atlantic thus exhibit a notable similarity to the Greenland ice isotopic record (Figure 5).

Parallel changes in surface- and deep-water oxygen isotopic ratios at these high northern latitudes also indicate pulses of low $\delta^{18}\text{O}$ deep-water export, particularly during stadial events. This suggests periods of deep convection along the glaciomarine margins by brine formation, as occurs today along the Ronne-Filchner ice shelves in the Weddell Sea.

Further south in the North Atlantic, between 55° and 40°N , the sedimentary signal is dominated by a succession of major ice-rafting events (HEs), occurring approximately every 5–10 ka (Figures 2, 3, and 6). This zone is called the Ruddiman Belt after Ruddiman (1997) (Figure 6) and constitutes the main melting zone for icebergs on their eastward journey along the polar front. The IRD material associated with the HEs has been clearly identified as deriving in large part from the Laurentide Archæan shield of Canada, which is from 3 to more than 4 billion years old, and with a significant component of metamorphosed carbonate and iron-coated minerals (Bond et al., 1992, 1993).

The material included in HE IRD is present in many sizes, from 1- μm -diameter clay to more than 1-mm-diameter sand

Figure 3 Comparison of the oxygen isotope ratios of stalagmite M1–2 from Socotra Island (Indian Ocean) with oxygen isotopes from the GRIP ice core (Johnsen et al., 2001) and the $\delta^{18}\text{O}$ record of a stalagmite from Hulu Cave in central China (Wang et al., 2001). The timescales are independent and shifted to give the best fit for DO events. The oxygen isotopic scales for the stalagmite records are reversed. The locations of DO events 9–13 as identified in each record are also shown. From Burns SJ, Fleitmann D, Matter A, Kramers J, and Al-Subbary AA (2003) Indian Ocean climate and an absolute chronology over Dansgaard/Oeschger events 9 to 13. *Science* 301: 1365–1367.

Figure 4 Submillennial asynchrony of Northern and Southern Hemisphere temperature change and of the surface- and deep-water T - $\delta^{18}\text{O}$ signature in the northeast Atlantic, as illustrated by (a) Greenland temperatures (data from Meese et al., 1997); (b) North Atlantic subpolar surface temperatures, recorded by the $\delta^{18}\text{O}$ of planktonic Foraminifera (spliced record from Skinner et al., 2003 and N. J. Shackleton, personal communication); (c) North Atlantic benthic $\delta^{18}\text{O}$ (spliced record from Skinner et al., 2003 and N. J. Shackleton, personal communication); (d) Southern Ocean surface temperatures, recorded by the Mg/Ca ratios of planktonic Foraminifera (Pahnke et al., 2003); and Antarctic temperatures (EPICA Community Members, 2004).

and pebbles. Some HEs, such as HE6 and HE3, are ‘anomalous’ in their characteristics because they contain more clastic material from the Arctic and Western Europe. These events appear to be associated in particular with periods of increased invasion of the ice shelves over the upper continental margins.

In the North Atlantic, each HE is associated with pronounced surface-water cooling, with a parallel $\delta^{18}\text{O}$ anomaly at high latitudes. The observed 1–2‰ drops in foraminiferal $\delta^{18}\text{O}$ would correspond to ~ 0.1 – 0.5 Sv ($1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$) of meltwater invading the North Atlantic for ~ 500 years. Corresponding sea-level changes are estimated at ~ 5 – 15 m, which is ~ 5 – 10% of the full glacial–interglacial amplitude. Cold events associated with HEs are also observed on the continents at similarly high latitudes. The Oldest, Older, and Younger Dryas climate events have been described in terrestrial pollen series for some time. Records of cold stadials corresponding to HEs during the glacial period have also been observed in European loess sections (indicated by changes in mollusk shells or the $\delta^{13}\text{C}$ of residual plant material), in pollen records from sediment cores on ocean margins, and in the isotopic ratio ($\delta^{18}\text{O}$ or $\delta^{13}\text{C}$) of cave stalagmites (Figure 3). These latter records have the advantage of being precisely dated using $^{230}\text{Th}/^{234}\text{U}$ dating with an error of ~ 500 years at 50 ka BP.

The impacts of DO and HE events have not been restricted to the high latitudes in the North Atlantic region.

Paleotemperature reconstructions from the North Pacific appear to indicate an antiphase relationship with respect to Greenland temperature (Figure 4). At mid-latitudes in the Pacific, highly detailed records from the Santa Barbara Basin indicate a very close coupling between local temperatures and Greenland temperatures. Benthic fauna and carbon isotope excursions in this basin also suggest a coupling between Greenland interstadials and decreased local bottom-water oxygenation, possibly accompanied by pulses of methane clathrate dissociation. In the Southern Ocean, millennial temperature changes have been observed between $\sim 40^\circ$ and 55°S (Figure 3), with cooling events apparently associated with colder conditions over Antarctica and with increased IRD supply from the Antarctic ice sheet. Preliminary chronologies suggest that these Southern Ocean IRD events occurred out of phase with the HEs observed in the North Atlantic. Hence, it appears that the DO cycles and HEs that have been recorded in the North Atlantic region have been associated with ‘southern counterparts,’ such that for each HE (at least) a corresponding ‘A event’ may be identified in Antarctica. These Antarctic A events, in contrast to their DO counterparts, are characterized by a relatively gradual warming (of $\sim 10^\circ \text{C}$ over a few millennia) followed by a slightly more prolonged cooling of similar amplitude. The specific character of Antarctic temperature change, and its relation to temperature variability recorded in Greenland, is discussed elsewhere in this encyclopedia.

Low-Latitude Signals

The best climate information obtained from low-latitude records is linked to changes in temperature, precipitation, and monsoon activity. Rapid temperature shifts, synchronous with Greenland variability across the last deglaciation, have been identified in the Cariaco Basin and the South China Sea, whereas temperature changes that are apparently synchronous with Antarctica have also been reconstructed in the tropical Atlantic just outside of the Cariaco Basin and in the Makassar Strait of the western tropical Pacific. Other apparently 'Antarctic-type' temperature changes have also been reconstructed for the last deglaciation (using the alkenone temperature proxy) in the Angola Basin of the southeast tropical Atlantic, although these have been interpreted as significantly lagging behind the changes in Antarctica and thus appear to be more synchronous with Greenland change (Figure 5).

The direct response of the Asian and African monsoons to the changing seasonality of insolation forcing has been well known for nearly two decades. The response of the monsoon

system to Northern Hemisphere rapid climate change is equally well marked, with dramatic reduction of the Indian summer monsoon (and its associated upwelling system in the Arabian Sea and low-salinity waters around Indonesia) during each DO stadial. Asian summer and winter monsoons were also affected (Figure 6), with significant summer monsoon increase during the main DO interstadials. The main DO stadials have seen a significant decrease in the main trade wind circulation and associated Hadley cell strength over the western Pacific, in a way similar to the conditions associated with El Niño events today. Some of the temperature shifts observed in the intertropical areas may be associated with these changes.

Millennial Changes in Deep- and Intermediate-Ocean Hydrography

The ocean's large-scale circulation is a key part of the Earth's climate system that is directly coupled with atmospheric circulation and composition, as well as the transport of heat and

Figure 5 Low-field magnetic susceptibility records (in 10^{-4} SI) reported versus depth (m) for a few representative cores from the northern Atlantic Ocean. The gray curves are typical for the Ruddiman Belt (see Figure 6), with peaks of high susceptibility during the Heinrich events, whereas the others show the short-term variations in which Heinrich layers (vertical lines) coincide with minima. Signals from core MD95-2009 and SU90-33, at $\sim 60^\circ$ N, present particularly strong similarities with the Greenland ice isotopic records (Figures 1, 2, and 6). From Kissel C (2005) Magnetic signature of rapid climate variations in glacial North Atlantic, a review. *Comptes Rendus Geoscience* 337: 908–918.

Figure 6 Distribution of high-susceptibility sediment associated with ice surge events HE1 and HE4. The colored area is at approximately the same location as the belt where sediment contains a large fraction of ice-rafted detritus described by Ruddiman (1977). Redrawn from Grousset FE, Labeyrie L, Sinko JA, et al. (1993) Patterns of ice-rafted detritus in the glacial North Atlantic (40–55° N). *Paleoceanography* 8(2): 175–211.

moisture across the globe. A large body of paleoceanographic evidence supports the hypothesis that the geometry of the world's surface-, intermediate-, and deep-water masses was significantly altered during past glacial climate regimes, and that this situation has also varied on millennial timescales (Labeyrie et al., 2002).

Some evidence has suggested that the variability of the Atlantic deep- and intermediate-water mass geometry during HEs and DO cycles has included an inverse relationship between the ventilation of glacial North Atlantic deep water (hereafter GNDW) and glacial North Atlantic intermediate water (GNAIW), with stadials coinciding instead with a reduced northern deep-water export and an increased northern intermediate water export. However, what is apparent from the paleoceanographic record is that both intermediate- and deep-water masses exported from the North Atlantic have been affected at least in part in antiphase with the export of their southern-sourced 'counterparts', the glacial analogues of Antarctic intermediate water (hereafter GAAIW) and Antarctic bottom water (hereafter GSDW). In particular, intense stadial events in the North Atlantic region appear to have been accompanied by an increased incursion of GSDW (at the expense of GNDW) into the deep Atlantic.

Millennial changes in the supply of *Mediterranean outflow water* (MOW) to the intermediate Atlantic are not well constrained, although it appears that a more restricted flow of MOW out of the Mediterranean and northward onto the Iberian Margin (due to lowered sea level and a shallower Mediterranean sill depth) was nonetheless more intensified during past glacial and, perhaps, stadial climate regimes, because it was colder, more saline, and hence more dense. In the Pacific, millennial intermediate- and deep-water variability was

closely connected with the changes experienced in the Atlantic. Thus, along with the apparently increased AAIW export in the intermediate Southern Ocean during North Atlantic DO stadials and HEs (Pahnke et al., 2003), there was a concurrent decrease, within the uncertainties of the age models, in the influence of NADW versus AABW in the deep Southern Ocean (which should also reflect the character of deep water entering the deep Pacific south of New Zealand), as well as an increase (at least across the last deglaciation) in the ventilation of the intermediate North Pacific. Thus, evidence suggests that the ventilation of the intermediate Pacific by both southern and northern sources increased during North Atlantic stadials, in 'antiphase' with the ventilation of the deep Atlantic by NADW and the intermediate Atlantic by GNAIW.

North–South Linkage

Any viable theory that proposes to explain past millennial climate change must be consistent with the geological record and must be capable of accounting for the observed patterns of climate change recorded in the Greenland and Antarctic ice cores and in any other records that can be securely linked to these. The relation between Greenland and Antarctic temperature change on millennial timescales is perhaps best described as 'asynchronous'; indeed, the fact that the two climate signals are distinct (rather than simply offset or in antiphase) is visually obvious but also statistically demonstrable.

Despite the stratigraphic difficulties involved in linking distal paleoclimate records with submillennial precision, it appears that stadial–interstadial temperature changes in Greenland and Antarctica have remained coupled with parallel

surface-water temperature changes recorded in the North Atlantic and Southern Ocean, respectively. The relation of Greenland and Antarctic temperature change to low-latitude climate variability is more ambiguous, although it appears that Greenland stadials (and hence expansions of the North Atlantic polar regime) have been coupled with synchronous increases in the dominance of winter precipitation in the Asian and Indian monsoons and with reduced precipitation in the Northern Hemisphere tropical Atlantic.

Testing the various mechanisms that are proposed to explain the Greenland–Antarctic asynchrony relies in many ways on assigning ‘Arctic’ or ‘Antarctic’ affiliations to records from throughout the globe. However, biases due to proxy seasonality and/or dating errors, as well as offsets between radiometric and ice core chronologies, remain significant hurdles to overcome in making precise ice core correlations for this purpose. One theory that proposes to explain north–south climate connections, the ‘bipolar seesaw’ in its most simplified form (Stocker and Johnsen, 2003), predicts that Atlantic tropical temperatures should either vary in antiphase with respect to Greenland temperatures or be correlated in some way with Antarctic temperatures. This prediction has been inadequately tested, although it is apparent that the precipitation sources of both Greenland and Antarctica (presumably in part of low-latitude origin) warmed significantly during Greenland stadials. It is very likely, if not certain, that the global connections associated with the Greenland–Antarctic asynchrony have been mediated by atmospheric processes and, therefore, that a better understanding of the intensities and positions of the main atmospheric frontal systems is required if we are to accurately interpret the available paleoceanographic evidence.

One of the most intriguing observations that affects the role of the deep-ocean circulation in millennial north–south connections is that the atmospheric coupling between Greenland and northeast Atlantic temperatures appears to have run parallel with an unexplained coupling between Antarctic temperature and benthic foraminiferal $\delta^{18}\text{O}$ from the deep northeast Atlantic (Shackleton et al., 2000; Figure 6). There is good evidence that changes in glacio-eustatic sea level may have played a role in the apparent Antarctic–deep Atlantic link. However, estimates of ice volume change can only partially explain the amplitude of the northeast Atlantic benthic $\delta^{18}\text{O}$ variability, and there is independent evidence that purely local hydrographic variability (i.e., local deep water $\delta^{18}\text{O}$ and temperature change) also contributed to the benthic isotopic excursions recorded in the deep Atlantic. Similar millennial benthic $\delta^{18}\text{O}$ changes to those observed in the deep Northeast Atlantic have been recorded in the intermediate Southern Ocean. Although this may indicate the existence of a strong millennial, global (glacio-eustatic) component in the marine $\delta^{18}\text{O}$ record (which was linked in some way to Antarctic temperature change), such an interpretation would need to be reconciled with parallel $\delta^{13}\text{C}$ evidence for concurrent pulses of (cold, fresh) AAIW export, which will also have left their mark on the Southern Ocean benthic $\delta^{18}\text{O}$ record. In addition, other records from the abyssal Southern Ocean show no millennial benthic $\delta^{18}\text{O}$ variability (hence no evidence of glacio-eustatic variability), although they do include clear indications of changes in local deep-water hydrography. The resolution of these intriguing questions is certain to set much-needed

constraints on the models that we may propose to flesh out or to supersede the bipolar seesaw concept.

Mechanisms of Millennial Climate Change: Modeling Efforts

The rapidly expanding suite of high-resolution paleoclimate records that exhibit millennial-scale variability has provided an enormous stimulus to numerical modeling efforts during the past decade. Much of this modeling has focused on the interaction of the ice sheets and the atmosphere–ocean circulation system, including the influence of high-latitude freshwater discharge on North Atlantic stratification, deep-water formation, and the associated meridional heat transport. Evidence from the geological record has been crucial in directing this modeling focus. Despite many advances, few model simulations have accurately reproduced the characteristic structure and timing of the ‘type events’ that are recorded in the Greenland and North Atlantic temperature records, for example. One difficulty involved in doing so derives from the fact that the characteristic recurrence time of DO events ($\sim 1\text{--}2\text{ ka}$) or HEs ($\sim 5\text{--}7\text{ ka}$) is much longer than the characteristic timescale of the ocean–atmosphere system ($\sim 0.1\text{--}1\text{ ka}$ at most). This suggests that millennial climate changes similar to those observed in the geological archives are not likely to derive from internally sustained oscillation in the ocean–atmosphere system alone and are more likely to have involved additional climate parameters with longer time constants, such as the cryosphere. Furthermore, based on the abrupt character of many climate transitions recorded in the geological archive, it is probable that past millennial climate change has involved the repeated crossing of stability thresholds that emerge from the interaction of the ocean, atmosphere, and cryosphere ‘subsystems.’

The role of the cryosphere in past millennial climate change is directly supported by geological evidence of the occurrence of massive iceberg discharges into the North Atlantic region during each DO stadial. Hence, a minimal model of millennial-scale climate variability should couple together the ocean, atmosphere, and ice sheets. Indeed, it is not clear how the ocean circulation could be correctly modeled without considering the atmospheric circulation, which in turn will respond sensitively to the altitude and extent of ice sheets and sea ice. Generally, there are two approaches to modeling the combined ice–ocean–atmosphere effects on millennial climate change. The first is to prescribe or parameterize the presumed impact of ice sheet variability (generally limited to prescribing the discharge of freshwater into the North Atlantic) and to determine the impact of this on the ocean–atmosphere system. The second approach involves directly modeling ice sheet dynamics and attempting to incorporate this into a coupled ocean–atmosphere model. Using the first approach, it has been possible to simulate entire sequences of millennial climate changes that bear a resemblance to the geological record. This has illustrated the plausibility of ice sheet discharges into the North Atlantic (or indeed the Southern Ocean) as triggers for climate change via their impact on ocean overturning and meridional heat transport. However, such models leave open the question of what physical mechanisms and specific climatic feedbacks ultimately drive ice sheet dynamics.

Direct modeling of ice sheet dynamics has independently confirmed the plausibility of recurrent ice sheet destabilization in principle. However, although the timing of modeled ice sheet discharges (~ 1 every 4500 years) is approximately consistent with the geological evidence, the amount of freshwater associated with the collapse of the Hudson Bay ice stream, for example, is small (order of magnitude ~ 0.01 Sv). Based on most (independent) ocean and ocean-atmosphere models, such a freshwater perturbation would be too small to induce a significant change in the North Atlantic density stratification and hence the Atlantic overturning circulation and regional climate.

In addition, modeled freshwater fluxes associated with individual ice sheet discharges do not agree with our best estimates of rapid sea-level change. Field reconstructions suggest millennial sea-level changes of at least ~ 10 m during the last glaciation, which would correspond to ~ 1 Sv sustained over ~ 100 years. This implies an integrated freshwater flux that is orders of magnitude larger than the regional values simulated by ice sheet models. A positive feedback mechanism that amplifies the effects of individual ice stream discharges must therefore exist, and it is possible that sea-level rise may provide such a mechanism by destabilizing grounded marine ice sheets and thus triggering multiple discharges at approximately the same time.

As discussed previously, the main climatic impact of ice sheet discharges is generally perceived in terms of their effect on the ocean overturning circulation. Perturbations of ocean circulation due to freshwater discharge have been modeled extensively with coupled climate models of varying complexity. In most cases, the fundamental behavior of the ocean circulation is drawn in terms of 'hysteresis loops' (forced oscillations between 'on' and 'off' states via different thresholds for each transition), wherein a primary difficulty lies in determining proximity of the system to a given threshold or, indeed, whether it ever crosses such thresholds. Hence, the degree of ocean circulation 'collapse' in various models is found to be sensitive to not only the amount and location of the freshwater input but also the model parameterization (including that of mixing and diffusive processes). Nevertheless, model experiments generally suggest that ~ 0.1 Sv or more of freshwater is needed to induce a significant change in North Atlantic overturning. Hence, the previous estimate of ~ 1 Sv over 100 years (based on sea-level evidence), if supplied to the North Atlantic, would be sufficient to shut down the Atlantic overturning circulation and cause surface temperature changes of up to $\sim 15^\circ\text{C}$ in the North Atlantic region.

In parallel with these effects (although only if the modeled circulation changes are large enough), models also predict a compensating warming in the Southern Hemisphere. This is consistent in principle with the so-called bipolar seesaw mentioned previously. The term bipolar seesaw has not always been used in the literature to designate the same physical process or even the same temporal relationship between Greenland and Antarctic climate change. Here, it is used to designate the simple principle of partially 'mutually exclusive' heat budgets in the north and south, which are physically connected via a mechanism that involves the Atlantic overturning circulation and the meridional heat transport of the ocean-atmosphere system. Although the bipolar seesaw

mechanism for linking millennial climate change in the Northern and Southern hemispheres remains a subject of intense debate, it is more or less generally held that the apparent north-south connection can be explained by a set of physical mechanisms that involved changes in the large-scale ocean circulation that responded to (and/or incurred) changes in atmospheric circulation, high-latitude sea ice distribution, and ice sheet stability. A variety of more specifically defined models have been built on this central, and rather theoretically sparse, ocean-atmosphere-cryosphere bipolar seesaw notion. Testing these various models with better and more widespread geological data is clearly a priority of current research.

Much has been learned from the modeling efforts of recent years, and yet much remains to be resolved, including the specific effects of mixing and diffusion processes at the ocean boundaries (i.e., due to wind stress) and in the ocean interior. It seems likely that a resolution of the bipolar seesaw controversy in particular (i.e., testing its existence in precisely defined terms) will provide a sound basis for modeling millennial climate change more generally.

Paleotempestology

Introduction

Paleotempestology is an emerging field of science that studies past tropical cyclone activity beyond the period of instrumental observations, typically spanning the last several centuries to six millennia. Tropical cyclones are known by different names in different regions of the world – *hurricanes* in North America, *typhoons* in the Northwest Pacific, and *cyclones* in South Asia and Australia. Here, the term *hurricanes* is sometimes used interchangeably with all other types of tropical cyclones.

In the United States, the instrumental record of tropical cyclone activity is essentially confined to the last 150 years and it is much shorter in other parts of the world. This record is too short to fully capture the occurrence of the rare but most destructive hurricanes – the ‘catastrophic’ hurricanes of category 4 and 5 intensity according to the Atlantic and Eastern Pacific Basins-based Saffir–Simpson scale. Therefore, by providing a long-term, empirical record of hurricane activity over the last 6000 years, paleotempestology has shown that it is useful for revealing the spatial and temporal variability of hurricane activity and deciphering its relationship with global climatic changes.

Two main sources of data are available for reconstructing past hurricane activity to beyond the instrumental period – geological proxy records, and historical documentary records. Therefore, they underscore two major approaches to the study of paleotempestology – geological and archival.

Geological Proxy Records

A landfalling hurricane is an important geological and ecological agent that can severely impact the landforms, ecosystems, and sedimentary and hydrological processes on the coast (Figure 1). These geophysical and ecological impacts may leave a geological record that can be deciphered by means of proxy techniques. Several geological or biological proxies have been successfully employed to reconstruct past hurricane strikes. So far, the most widely used proxy is overwash sand layers deposited in the sediments of coastal lakes, marshes, and swamps (Donnelly and Webb, 2004; Liu, 2004; Liu and Fearn, 1993). Storm-built beach ridges in Australia have also been shown to contain a record of cyclone strikes spanning the past 6000 years (Nott, 2011; Nott and Hayne, 2001; Nott et al., 2009). In addition, oxygen isotope values extracted from tree rings and stalagmites have been deciphered to contain a record of past tropical cyclone activity affecting coastal regions (Frappier et al., 2007; Miller et al., 2006; Nott et al., 2007).

Overwash Sand Layers in Coastal Back-Barrier Lakes

When a hurricane makes landfall, the strong onshore winds, especially in the forward-right quadrant of the intense low-pressure system, will generate a storm surge directed toward

the coast. Generally speaking, stronger and larger hurricanes correspond with higher storm surges. For intense hurricanes, the storm surge plus the wave runup may overwash the coastal barrier, causing sand to be eroded from the beach or dunes and deposited in the lake or marsh behind it. Stratigraphically, the overwash fan will exist in the form of a sand layer, which is thickest near the shore and thins out toward the center of the lake (Liu, 2004; Liu and Fearn, 1993, 2000a). In a coastal back-barrier lake that had been subjected to repeated overwash events in the past, the sediment stratigraphy should contain multiple sand layers that contain a stratigraphic record of intense hurricane strikes (Figure 2). These sand layers are composed of fine to coarse sand that is usually well sorted, and have abrupt contacts with the more organic, finer, and darker sediments both above and below. Their thickness may range from a few mm to more than 10 cm (Figure 3). They can be identified either visually or by means of sedimentological techniques such as loss-on-ignition analysis and grain-size analysis of core samples (Donnelly and Woodruff, 2007; Liu and Fearn, 2000a; Yu et al., 2009).

The attribution of these sand layers to overwash processes can be verified by using supplementary proxies such as marine microfossils (e.g., dinoflagellates, marine diatoms, Foraminifera) that suggest seawater intrusion (Hippensteel and Martin, 1999; Liu et al., 2008; Scott et al., 2003; Williams, 2010), opal phytolith assemblages that are derived from sand dunes (Lu and Liu, 2005), or geochemical signals that suggest beach or bay origin of the transported material (Donnelly, 2005; Woodruff et al., 2009). A chronology of past overwash events or hurricane strikes can be established by means of radiometric dating techniques such as radiocarbon (^{14}C), lead-210 (^{210}Pb), or cesium-137 (^{137}Cs) dating, which may be supplemented by using stratigraphic markers such as pollen and lead pollutants (Donnelly and Webb, 2004; Liu et al., 2008). For any particular location, the return period of hurricanes of a specific intensity category can be calculated by tallying up the number of events occurring over a given period of time (Liu, 2004).

The intensity of the paleohurricanes may be harder to infer from the proxy record than their frequencies. As a first approximation, it can be assumed that stronger hurricanes tend to produce higher storm surges and thus more extensive overwash fans. Therefore, within the same core, sand layer thickness can be used as a rough indicator of storm intensity (Figure 4). The sedimentary impact of recent hurricanes of known intensity can be used as a modern analog for calibrating the intensity estimate of paleohurricanes. For example, on the basis of sediment-stratigraphic evidence that the overwash sand layer deposited by Hurricane Frederic, a category 3 hurricane that struck Alabama in 1979, was only confined to the near-shore sediments, Liu and Fearn (1993) inferred that older sand layers that occurred in cores taken from the center of Lake Shelby (where the Frederic sand layer was absent) must have been deposited by prehistoric hurricanes of category 4 or 5 intensity.

Figure 1 Environmental impacts of catastrophic hurricanes. Modified from Liu K-b (2004) *Paleotempestology: Principles, methods, and examples from Gulf Coast lake sediments*. In: Murnane RJ and Liu K-b (eds.) *Hurricanes and Typhoons: Past, Present, and Future*, pp. 13–57. New York: Columbia University Press. A landfalling hurricane may cause a storm surge that overtops beach barriers, resulting in the formation of an overwash fan and the deposition of a sand layer in the sediments of a back-barrier lake or marsh. The strong wind may cause massive damage or mortality to trees, leaving behind a paleoecological record of disturbance and succession, including the occurrence of posthurricane fires. Heavy precipitation may cause flooding in the lowlands, and soil erosion and landslide in the uplands. The $\delta^{18}\text{O}$ -depleted signal in the hurricane rains may be recorded in the cellulose of tree rings and the calcium carbonate of speleothems and coral skeletons if it is not attenuated by hydrological processes.

Figure 2 Hypothetical pattern of sand layer deposition in a coastal lake subjected to repeated storm overwash events in the past. The overwash sand layers are thicker near the sand barrier and become thinner toward the lake center. A core taken from site B will contain more and thicker sand layers than the one taken from site C. A core taken from site A, however, may consist of all sand without discrete layers. Reproduced from Liu K-b (2004) *Paleotempestology: Principles, methods, and examples from Gulf Coast lake sediments*. In: Murnane RJ and Liu K-b (eds.) *Hurricanes and Typhoons: Past, Present, and Future*, pp. 13–57. New York: Columbia University Press.

Coastal lakes from Alabama and northwestern Florida have yielded proxy records of catastrophic (category 4 and 5) hurricane strikes that span the last 5000 years (Liu and Fearn, 1993, 2000a).

In addition to storm layer thickness, grain size can also be used as an indicator of storm intensity based on the principle that compared with weaker storms, stronger storms generate bigger waves and higher storm surges, which in turn have

greater energy to transport coarser sediments to the coring site. On the basis of grain-size data of sand layers in cores taken from a back-barrier lake, Woodruff et al. (2008) applied a simple advective-settling model to constrain the coastal flooding intensities (which are taken to be a function of storm intensity) required to transport clastic sediments to various distances behind the barrier during overwash processes. Grain size has been used as a principal indicator for

Figure 3 Photograph of three prominent sand layers in the 50–78 cm segment of core 9 from Western Lake, northwestern Florida, and the corresponding water and organic matter content curves determined by loss on ignition. Radiocarbon dates are on the right. Reproduced from Liu K-b and Fearn ML (2000) Reconstruction of prehistoric landfall frequencies of catastrophic hurricanes in northwestern Florida from lake sediment records. *Quaternary Research* 54: 238–245.

paleointensity reconstruction in studies from a back-barrier tidal lagoon in western Texas (Wallace and Anderson, 2010) and an atoll reef lagoon fringed by wave-transported coral boulders in the South China Sea (Yu et al., 2009).

As a rule of thumb, stronger storms tend to be rarer than weaker ones. Thus for any particular site, a statistical relationship exists between hurricane return periods (frequency) and hurricane return levels (intensity) in the historical record of storm activity. Elsner et al. (2008) have developed a statistical model that quantitatively links the frequency and intensity data in the historical record (AD 1851–2005) for the Lake Shelby area. By applying this statistical relationship to the proxy-derived frequency estimate of 11 events over 3500 years (or a return period of 318 years), they inferred that the sand layers in the proxy record of this lake were probably deposited by paleohurricanes with wind speeds of at least 64 m s^{-1} or category 4 or 5 intensity.

Proxy Records from Coastal Marshes and Other Coastal Sites

The same principle and research methods can be applied to coastal back-barrier wetlands (marshes and swamps) for generating proxy records of past hurricane strikes (Donnelly and Webb, 2004; Donnelly et al., 2001a,b, 2004). These back-barrier wetlands are typically peat-accumulating environments situated behind barrier beaches. As in coastal lakes, overtopping of the barrier beach by storm surge will lead to the formation of an

overwash fan behind the barrier, which will be expressed stratigraphically as a sand layer sandwiched between marsh peat (Figure 5). If the barrier beach is breached by the storm surge to form an inlet, a large flood-tidal delta may be formed across the back-barrier marsh, which may even extend into the lagoon or bay behind it (Donnelly and Webb, 2004). Well-dated proxy records of recent and prehistoric hurricane strikes have been obtained from back-barrier marshes in Rhode Island, New Jersey, and New York (Donnelly et al., 2001a,b; Scileppi and Donnelly, 2007). Similarly, millennial proxy records of paleo-hurricane strikes have been identified from back-barrier mangrove or palmetto swamps in Belize (McCloskey and Keller, 2009). In the Chenier Plain of southwest Louisiana, the storm surge deposit laid down by Hurricane Rita in a coastal woodland (ridge) and marsh (swale) environment was studied in detail with regard to its stratigraphy, sedimentology, and Foraminifera content (Williams, 2009), which may provide a modern analog for identifying prehistoric storm deposits in older sediments in similar geomorphic settings.

Estuarine or deltaic marshes formed near the mouth of major rivers and along tidal inlets can also provide proxy records of past hurricane strikes (Liu and Fearn, 2000b; Scott et al., 2003). A beach barrier may or may not be present, but these marshes are inundated by the storm surge during an intense hurricane strike. Stormy waves and the storm surge may stir up the silt and mud from the bottom of the adjacent bays, and a layer of lagoonal mud will be deposited on the

Figure 4 Model showing the positive relationship among hurricane intensities, extent of overwash fans, and thickness of sand layers in sediment cores. Reproduced from Liu K-b and Fearn ML (2000) Reconstruction of prehistoric landfall frequencies of catastrophic hurricanes in northwestern Florida from lake sediment records. *Quaternary Research* 54: 238–245. Top: Hypothetical sedimentary stratigraphies of 11 cores (#1–11) taken from different parts of a lake impacted by intense hurricanes and associated overwash events six times during the past 3000 years. Thick and thin sand layers are represented by cross-shaded bands and dotted lines, respectively. Bottom: Hypothetical pattern of overwash sand deposition in the lake where the 11 cores were taken. Solid, dotted, or dashed lines inside the lake denote the horizontal extents of the six overwash fans (labeled A–F) corresponding to the six hurricane strikes and overwash events (arrows). Thicknesses of the arrows are proportional to the intensity of the hurricanes according to the Saffir–Simpson scale, the latter also designated by the circled number below each arrow. Numbered black dots (#1–11) represent cores taken from the lake.

marsh surface, forming a storm deposit. This storm deposit may consist of sand, silt, or clay, depending on the hydrodynamic conditions of the storm surge and the sediment supply. This layer may also be recognized by the presence of marine microfossils such as dinoflagellates and offshore calcareous Foraminifera. Abruptly terminated oyster-shell layers in a

core may also be interpreted as indicators of storm events, as oyster beds may be buried and killed by thick storm deposition (Scott et al., 2003). Proxy records spanning 5000–6000 years have been obtained from several estuarine/deltaic marshes and tidal inlets in Louisiana, Mississippi, and South Carolina (Liu, 2004; Liu and Fearn, 2000b; Scott et al., 2003).

Figure 5 Photographs of overwash sand layers in back-barrier marsh sediments. (a) Three sand layers near the top of a core from Little Harbor Marsh, Massachusetts, deposited by three historic hurricanes: Bob (1991), Carol (1954), and the 1938 Hurricane. (b) Two sand layers in cores taken from Succotash Marsh, Rhode Island, deposited by Hurricane Carol (1954) and the 1938 Hurricane. (c) Two sand layers deposited by the same hurricanes are exposed in a stratigraphic section at Barn Island Marsh, Connecticut. Reproduced from Donnelly JP and Webb T III (2004). Backbarrier sedimentary records of intense hurricane landfalls in the northeastern United States. In: Murnane RJ and Liu K-b (eds.) *Hurricanes and Typhoons: Past, Present, and Future*, pp. 58–95. New York: Columbia University Press.

A rather unusual proxy record was obtained from a currently nontidal meromictic (chemically stratified) lake near Boston, Massachusetts (Besonen et al., 2008). Annually laminated, or varved, sediments deposited in Lower Mystic Lake are interrupted by up to 36 anomalous graded beds that have been interpreted to be deposited by strong hurricane-related flooding events in the lake basin during the past millennium. While their depositional mechanisms remain uncertain and may also involve some nontropical aspects, 10 out of 11 of the most prominent graded beds deposited during the historical period correspond chronologically with the years in which strong hurricanes affected the Boston area. A likely explanation is that strong hurricane winds and intense rainfall caused vegetation disturbance and intensified soil erosion in the watershed, resulting in the formation of these graded, flood deposits (Besonen et al., 2008).

Beach Ridges as Paleohurricane Proxy

While sediments from coastal lakes and wetlands have proven to be the most useful data archive in paleotempestology, other natural archives and proxies have recently been developed. In the coastal zones of northeastern, northern, and western Australia, chronostratigraphic series of shore-parallel beach ridges have been interpreted as proxy records of tropical cyclone strikes spanning up to the last 7000 years (Forsyth

et al., 2010; Nott, 2011; Nott and Hayne, 2001; Nott et al., 2007, 2009; Figure 6). Depending on the supply of source materials, these beach ridges may be composed of pure sand, coral rubble, or pure marine shells or a mixture of these. At each coastal location, typically 10–30 beach ridges are present, and they typically stand between 3 and 6 m above mean sea level (Nott et al., 2007). Their stratigraphy and chronology suggest that they are built by individual storm events as a result of marine inundation and wave transportation of source materials. Dating of successive ridges, usually by the radiocarbon (^{14}C) or optically stimulated luminescence (OSL) method, thus provides a chronological record of past cyclone strikes at that location. The average interval between the emplacement of successive ridges can be taken as a measure of the return period of cyclone events. Intervals generally in the order of 200–300 years have been reported from various coastal locations in Australia (Nott et al., 2007; Nott et al., 2009).

Paleocyclone intensity can be inferred from the elevation of individual ridges based on the assumption that ridge height represents the minimum height of the storm inundation, which is a function of storm intensity. A study using numerical storm surge and wave models suggests that virtually all the beach ridges in northeastern and northern Australia were formed by catastrophic cyclones of category 5 intensity, while those in western Australia were probably emplaced by category 2–4 cyclones (Nott, 2003, 2011; Nott et al., 2007).

Figure 6 Beach ridge plain at Cowley Beach in Queensland, Australia, consisting of 29 shore-parallel sand-dominated beach ridges that provide a proxy record of cyclone activity over the past 5500 years. Reproduced from Nott J (2007) The importance of quaternary records in reducing risk from tropical cyclones. *Palaeogeography, Palaeoclimatology, Palaeoecology* 251: 137–149.

Figure 7 Detrended $\delta^{18}\text{O}$ ‰ record of landfalling cyclones from AD 1228 to 2003 reconstructed from a stalagmite collected from Chillagoe, Queensland, Australia. Reproduced from Nott J (2007) The importance of quaternary records in reducing risk from tropical cyclones. *Palaeogeography, Palaeoclimatology, Palaeoecology* 251: 137–149. The thick horizontal line at -2.50 ‰ denotes a critical value for moderate-to-severe hazard impact attributable to intense cyclones.

Stable Isotopes in Tree Rings and Stalagmites

Another new and promising proxy is the stable isotopic signal preserved in the cellulose of tree rings and the calcium carbonate of stalagmites in limestone caves. Due to intense convection and the fractionation process, rainwater produced by hurricanes has a highly depleted oxygen isotopic signal (i.e., more negative $\delta^{18}\text{O}$ values) compared with that of low-latitude thunderstorms (Lawrence and Gedzelman, 1996). After a hurricane strike, this isotopically depleted signal from the intense hurricane rains may persist in surface or soil water for several weeks before it is attenuated, and may be incorporated into the growth rings of trees and speleothems (cave deposits) in the storm-affected region. A key to applying the

$\delta^{18}\text{O}$ proxy in paleotempestology lies in the ability to sample these annually banded archives and to detect the isotopically depleted signals at subseasonal resolutions, which can now be accomplished through microsampling techniques. Miller et al. (2006) produced a 220-year record of tropical cyclone activity in southern Georgia based on oxygen isotope values extracted from α -cellulose in the latewood portion of longleaf pine tree rings. Similarly, in a feasibility study, Frappier et al. (2007) presented a 23-year (1977–2000) stalagmite record of oxygen isotopic values from Belize that contain multiple negative excursions corresponding to known hurricane rain events in the historical record. A 777-year (AD 1226–2003) stalagmite $\delta^{18}\text{O}$ record obtained from a limestone cave at Chillagoe in

northeastern Queensland, Australia, reveals significant century-scale variability in tropical cyclone activity (Nott et al., 2007; Figure 7).

Paleohurricane Activity and Global Climate Changes

Since the early 1990s, more than two dozen proxy records of paleotropical cyclone activity have been produced from different parts of the world, mainly from the Atlantic and Gulf coasts of North America, the Caribbean region (including Central America), Australia, and the western Pacific (China and Japan). These paleo-records provide a long-term perspective in global hurricane activity, which is vital for understanding the relationships between hurricane activities and global climate changes and their possible controlling mechanisms.

These proxy records reveal that from region to region tropical cyclone activity exhibit long-term variations on timescales of centuries to millennia. On the Gulf of Mexico coast, a hyperactive period existed 3800–1000 years ago, which was preceded and succeeded by relatively quiescent periods during 5000–3800 cal year BP and 1000–0 year BP, respectively (Liu and Fearn, 2000a; Figure 8). A 5400-year proxy record from Puerto Rico in the northern Caribbean suggests that active periods occurred 5400–3600, 2500–1000, and 250–0 years ago, separated by relatively quiet periods in between (Donnelly and Woodruff, 2007). However, a new proxy record from southwestern Japan also suggests increased typhoon activity during 3600–2500 year BP and 1000–300 year BP (Woodruff et al., 2009). Conversely, beach ridge plain chronologies from northeastern and northern Australia exhibit two major gaps in ridge formation, which were interpreted to represent quiescent periods around 3400–2500 year BP and 1500–500 year BP (Forsyth et al., 2010), while a major gap of around 5400–3700 year BP was found in Western Australia (Nott, 2011). On a centennial timescale, the stalagmite $\delta^{18}\text{O}$ record from northeastern Australia shows that over the last 800 years, as many as seven cyclone events occurred during an active period from AD 1600 to 1800, compared with only 1, 2, and 0 events during the other bicentennial periods of AD 1800–2000, 1400–1600, and 1200–1400, respectively (Nott et al., 2007; Figure 7).

Two scenarios have emerged to explain the millennial-scale variations in Atlantic hurricane activity observed in the proxy record. Liu and Fearn (2000a) proposed the ‘Bermuda High hypothesis,’ which evokes long-term shifts in the position of the Bermuda High, the subtropical anticyclone that steers many intense hurricanes (especially the ‘Cape Verde’ type of hurricanes) westward across the tropical Atlantic ocean toward North America. According to this hypothesis, a southwestward shift of the Bermuda High would steer more hurricanes toward the Gulf coast, thereby resulting in hyperactivity such as that detected in the Gulf coast proxy record 3800–1000 years ago, whereas a northeastward shift would steer more hurricanes to hit the Atlantic coast (Liu and Fearn, 2000a; Figure 9). This hypothesis implies an antiphase relationship between the Gulf coast and the Atlantic coast. Such an inverse relationship is supported by a statistical analysis that links the historical records of hurricane activity from the Gulf and Atlantic coasts with the North Atlantic Oscillation (NAO), which is related to the position of the Bermuda High

Figure 8 Chronostratigraphic patterns of overwash sand layers (horizontal bars) representing catastrophic hurricane strikes over the last 4500 years documented at four sites along the Gulf coast from west to east: Pearl River Marsh (Louisiana), Pascagoula Marsh (Mississippi), Lake Shelby (Alabama), and Western Lake (Florida). Reproduced from Liu K-b (2004) *Paleotempestology: Principles, methods, and examples from Gulf Coast lake sediments*. In: Murnane RJ and Liu K-b (eds.) *Hurricanes and Typhoons: Past, Present, and Future*, pp. 13–57. New York: Columbia University Press. The clustering of events between approximately 1000 and 3400 ^{14}C years BP (before present) suggests the occurrence of a hyperactive period bracketed by relatively quiet periods. Each site was directly struck by catastrophic hurricanes 9–12 times during the last 3400 ^{14}C years (or 3800 calendar years), suggesting a return period of approximately 350 years.

(Elsner et al., 2000). Paleoclimatic records from North America and adjacent regions are consistent with the scenario of a southwestward shift in the Bermuda High 4000–3000 years ago (Liu and Fearn, 2000a). The proxy record from South Carolina on the Atlantic coast also seems to support the Bermuda High hypothesis (Scott et al., 2003).

The proxy record from Puerto Rico forms the basis of a competing scenario. Donnelly and Woodruff (2007) found that the paleohurricane activities recorded in Laguna Playa Grande correspond negatively with the proxy record of El Niño events, but positively with the proxy record of monsoonal precipitation in tropical Africa, suggesting that Atlantic hurricane activity is strongly modulated by large-scale circulation

Figure 9 Postulated changes in paleoclimatic conditions and in the position of the Bermuda High around 6000 year BP (a) and 3000 year BP (b) and their impacts on the predominant tracks of catastrophic hurricanes. Reproduced from Liu K-b and Fearn ML (2000) Reconstruction of prehistoric landfall frequencies of catastrophic hurricanes in northwestern Florida from lake sediment records. *Quaternary Research* 54: 238–245. Top: A more northeasterly position of the Bermuda High around 6000 years ago would have resulted in more landfalls on the Atlantic coast. Bottom: A shift of the Bermuda High to a more southeasterly position near the Caribbean around 3000 years ago probably steered more catastrophic hurricanes to hit the Gulf coast.

Figure 10 Comparison of reconstructed paleohurricane frequency record from Puerto Rico (top) with reconstructed El Niño frequency record from Ecuador (bottom) and reconstructed West African monsoon precipitation record from West Cameroon. Reproduced from Donnelly JP and Woodruff JS (2007) Intense hurricane activity over the past 5,000 years controlled by El Niño and the West African monsoon. *Nature* 447: 465–468. Periods of low paleohurricane activity in Puerto Rico (gray vertical bars) seem to correspond with the times of frequent El Niño events and low monsoonal precipitation in West Africa.

features such as El Niño/Southern Oscillation (ENSO) and the strength of the West African monsoon (Figure 10). This scenario implies that hurricane activity regimes in different coastal regions across the Atlantic basin would be both in-phase and synchronous, as they are governed by the same set of large-scale climatic factors that affect the rise and fall of hurricane activity. Mann et al. (2009) have produced a curve of basin-wide hurricane frequency indices for the past 1500 years on the basis of a compilation of proxy records in the Atlantic basin.

Historical Documentary Records

For the historical period during which written records are available, information about past tropical cyclone activity can be extracted from documentary sources derived from books or other data archives. The length of time covered by these documentary records varies from one region of the world to another, but it rarely exceeds a few hundred to a thousand years. Though comparatively short in time span, an advantage of these historical documentary records over the geological proxy data is that they usually have very high temporal resolution and precision, typically allowing reconstruction to the year, month, day, and even hour of the event. Many records contain wind direction that can be used to construct storm tracks (e.g., Mock et al., 2010). Some historical records contain reliable barometric pressure data, enabling precise calculations for determining storm intensity.

US Data Sources and Reconstructions

For the Atlantic Basin including the United States, 6-hourly data on the positions and intensities (central pressures and wind speeds) of all known hurricanes and tropical storms in the past one and a half centuries since 1851 are available at the National Hurricane Center's North Atlantic hurricane

database, or HURDAT (Landsea et al., 2004). For the historical period from the sixteenth to the nineteenth century, information about hurricane activity largely comes from documentary sources, including newspapers, plantation diaries, and some instrumental weather records (Chenoweth, 2006; Mock, 2004). Several major inventories of historical hurricanes affecting the United States and the Atlantic Basin (including the Caribbean and Gulf of Mexico region) have been compiled (e.g., Chenoweth, 2006; Fernandez-Partagas and Diaz, 1996; Ludlam, 1963). These documentary data, often narrative and spatially uneven, can be quantified and statistically analyzed to reveal the frequency patterns of hurricane strikes for selected regions. For example, a 223-year time series of tropical cyclone frequencies for South Carolina from AD 1778 to 2000 has been compiled (Mock, 2004). This time series reveals that two periods of unprecedented, very active tropical cyclone activity occurred in the 1830s and from 1880 to 1910 (Figure 11). A similar reconstruction has also been produced for Louisiana for the period 1799–2007 on the basis of a variety of historical records from United States, British, and Spanish sources (Mock, 2008). This time series also shows that Louisiana was impacted by hurricanes more frequently during the nineteenth century than during the twentieth century.

Spanish and British Archives

For the Caribbean region, documentary evidence derived from the aforementioned data sources in the United States or from local newspapers, diaries, or annals in the Caribbean has been used to compile inventories of hurricane activity during the past five centuries (e.g., Chenoweth, 2003; Chenoweth and Divine, 2008; Millas, 1968). However, two vast sources of documentary data have been used for reconstructing the frequency patterns of historical hurricane activity – Spanish archives and British archives (Chenoweth, 2006; Garcia Herrera et al., 2004, 2007). Much unexploited French sources remain to be utilized for this type of research. The Spanish

Figure 11 Time series of tropical cyclones affecting Charleston, South Carolina, from AD 1778 to 2000, reconstructed from local newspapers, plantation diaries, and early instrumental records. Reproduced from Mock CJ (2004) Tropical cyclone reconstructions from documentary records: Examples for South Carolina, United State. In: Murnane RJ and Liu K-b (eds.) *Hurricanes and Typhoons: Past, Present, and Future*, pp. 121–148. New York: Columbia University Press. The vertical bars represent annual frequencies (right axis) and the continuous line represents the 5-year running mean (left axis).

Figure 12 Time series of hurricanes (top) and storms (bottom) occurring in the Caribbean basin from the sixteenth to the nineteenth century, reconstructed from Spanish documentary evidence preserved in the Archivo General de Indias (AGI). The term storm refers to any event of excessive wind that lacks a clear indication of the occurrence of a shift in wind direction typically associated with the vortex of a hurricane. This category may include, among others, less intense tropical storms, extratropical storms, squall lines, and strong frontal passage episodes. Reproduced from Garcia Herrera R, Gimeno L, Ribera P, and Hernandez E (2005) New records of Atlantic hurricanes from Spanish documentary sources. *Journal of Geophysical Research* 110: D03109.

archives consist of millions of official documents recording all aspects of daily life in the Spanish colonies in the Americas from the Columbian contact to the nineteenth century. Most of these colonial documents are preserved in the Archivo General de Indias (AGI) in Seville, and several other archives in Madrid and Valladolid. The British archives, mainly starting in the mid-seventeenth century and covering a shorter time span than their Spanish counterparts, principally consist of mariners' logbooks kept on board Royal Navy ships during the period of English colonization of the Caribbean and related colonial papers found at the United Kingdom National Archives in London. British newspapers, available from the British Library, also based in London, supplement these colonial archives (Chenoweth, 2006; Chenoweth and Divine, 2008). The potential of all these colonial archives as a rich data source for paleotempestology is high, but work has only begun to fully exploit this potential due to the vast amount of documents contained in them, which extends well beyond the Atlantic Basin (Garcia Herrera et al., 2004, 2007; Mock, in press). An example of a reconstruction of Caribbean hurricane and storm activity for the period AD 1500–1900 using the Spanish archives shows two active periods in the sixteenth and the eighteenth centuries separated by a relatively inactive period in the seventeenth century, with the activity peaking during 1766–80 (Garcia Herrera et al., 2005; Figure 12).

Chinese Documentary Records and Guangdong Typhoon Time Series

By far, the longest documentary record of tropical cyclone activity can be found in China, where the historical record of typhoon landfalls spans more than 1000 years. Abundant information on typhoon landfalls can be found in the official histories commissioned by the central imperial government

(*zhengshi*), Veritable Records (*shilu*) of the Emperor's daily activities, semiofficial local gazettes (*fang zhi*) written by scholars at the county, district, or provincial level, and unofficial literary works such as personal diaries, travel logbooks, and poems (Louie and Liu, 2004). These Chinese historical sources reveal that the term *jufeng* was coined as early as AD 470 to designate typhoon (a wind that comes in all four directions) as a specific meteorological phenomenon that is distinct from other kinds of storms (Louie and Liu, 2003). A typhoon that struck the Shandong Peninsula in eastern China in AD 816 is probably the earliest recorded tropical cyclone landfall in the world (Louie and Liu, 2003).

Among the four sources of Chinese documentary data mentioned earlier, the local gazettes or *fang zhi*, especially those kept by coastal counties in southern and eastern China, are the richest data source for historical typhoon landfalls. For the majority of counties in China, there is at least one volume of county gazette that is accessible in a public library in China or overseas. Liu et al. (2001) have produced a 935-year time series of typhoon landfalls for the Guangdong Province of southern China spanning the period from AD 975 to 1909 based on data extracted from local gazettes (Figure 13). This 1000-year record of tropical cyclone time series – the longest in the world – reveals an approximately 50-year periodicity that may be linked to the Pacific Decadal Oscillation (PDO; Liu et al., 2001). The data also show two prominent peaks in Guangdong typhoon activity occurring at AD 1660–80 and AD 1850–80. Remarkably, these two typhoon maxima coincide with two of the coldest and driest episodes in northern and central China during the Little Ice Age (Figure 14). Liu et al. (2001) hypothesized that the apparent increase in typhoon activity in Guangdong during these cold episodes was caused by a southward displacement of the storm tracks associated with an intensification of the westerlies and a southward shift of the

Figure 13 Time series of typhoons striking Guangdong Province, southern China, from AD 1000 to 1909, reconstructed from Chinese local gazette (*fang zhi*) records. The vertical bars represent annual frequencies and the continuous line represents the 21-year running mean. Reproduced from Liu K-b, Shen C, and Louie KS (2001) A 1000-year history of typhoon landfalls in Guangdong, southern China, reconstructed from Chinese historical documentary records. *Annals of the Association of American Geographers* 91: 453–464.

subtropical high-pressure system, resulting in more typhoons making landfall in Guangdong while fewer striking the coastal provinces further north. Statistical analysis of modern and historical typhoon data from the western Pacific suggests that more frequent occurrence of La Nina conditions may also have caused a change in the predominant storm tracks, resulting in more typhoons moving straightly westward to hit Guangdong instead of recurving northwest to hit Japan (Elsner and Liu, 2003).

Research Needs and Future Research Directions

Paleotempestology is a relatively young science that started in the early 1990s (Liu and Fearn, 1993). The term paleotempestology was coined by Kerry Emanuel at the Massachusetts Institute of Technology (MIT) in 1998. It has since developed significantly in scope, in theory and methods, and in the number of practitioners. The following research needs and directions can be envisioned in the near future:

1. Expansion of geographical coverage and spatial data network: Early proxy work in paleotempestology started in the Gulf of Mexico coast, but more recently, proxy records have been obtained from the US Atlantic coast, the Caribbean region, Australia, and China and Japan. However, there is still a strong need for more well-validated and well-dated proxy records from all the tropical cyclone-prone regions of the world. For example, proxy records have yet to be published from the western coast of Mexico, which is impacted by hurricanes from the Eastern North Pacific basin.
2. Development of new proxies and archives: A promising research direction in paleotempestology involves the development of multiproxy techniques in detecting the geophysical and ecological impacts of past hurricanes. To date, the proxy that has been proven to be most effective in paleotempestology is the overwash sediments preserved in coastal lakes and wetlands, while beach ridge chronology has also been developed as a useful tool in Australia. Significant methodological advances have been made in the development of new proxies such as stable isotopic signals in tree rings, speleothems, and corals, but more calibration and sensitivity studies (e.g., Lewis et al., 2011) are needed to refine these promising techniques.
3. Coupling of geological and documentary archives: The voluminous documentary records in the Spanish, British, French, United States, Canadian, Chinese, and other colonial archives have barely been exploited for the reconstruction of tropical cyclone activities during the past centuries. Much more needs to be done. Wherever both geological and documentary records exist, they should be integrated for data calibration and comparison.
4. Improved calibration of proxy records with modern analog studies: While the frequency of past hurricane strikes can be estimated by enumerating the overwash sand layers in a core, the reconstruction of paleohurricane intensity is a more challenging task in paleotempestology. Regardless of the proxies or archives being used, intensity reconstruction for paleohurricane events can be improved by better understanding of the environmental impacts and/or sedimentological signatures of modern hurricanes of known intensities. For example, recent intense hurricanes such as Camille, Andrew, Hugo, Ivan, Katrina, and Rita can be used as modern analogs to aid proxy-based paleohurricane intensity reconstructions.
5. Integration of proxy data with modeling results: Another approach in improving the intensity estimate for paleohurricanes from proxy data is by means of computer modeling experiments. Storm surge modeling can simulate the overwash processes under various boundary conditions with regard to hurricane intensity, oceanographic response, and coastal terrain characteristics (e.g., Cheung et al., 2007). These modeling results can be integrated with the proxy record to help validate the intensity estimates.
6. Statistical applications in paleotempestology: When coupled with the historical hurricane record, proxy data can improve our estimates of the hurricane risk in a region by providing a longer, though chronologically less precise, record of past events, especially the extreme events. These historical and proxy data can be used in the statistical modeling of wind speed exceedance probabilities.

Figure 14 Comparison between (g) the Guangdong typhoon time series (21-year running mean) with other paleoclimatic time series from China and the Northern Hemisphere for the last millennium: (a) phenologically derived temperature in China, (b) winter temperature in the lower Yangtze river valley, (c) number of Chinese counties affected by drought, (d) frequency of dust rains in China, (e) tree-ring-based reconstruction of April-to-July precipitation in Huashan, north-central China, and (f) northern hemisphere temperature anomaly derived from a variety of paleoclimatic data sources. Reproduced from Liu K-b, Shen C, and Louie KS (2001) A 1000-year history of typhoon landfalls in Guangdong, southern China, reconstructed from Chinese historical documentary records. *Annals of the Association of American Geographers* 91: 453–464. The two peaks in Guangdong typhoon activity in AD 1660–80 and 1850–80 correspond to two of the coldest and driest episodes in central and northern China during the Little Ice Age.

Advanced statistical techniques such as Bayesian analysis and extreme value theory can be applied to the modern and proxy data to reduce the uncertainty of error estimates and to improve the assessment of hurricane risks along the coast. Work has just begun in this research direction in paleotempestology (Elsner et al., 2008).

Introduction

A thorough review of the global Younger Dryas oscillation is a difficult task, not possible to be covered completely in this article. The approach taken here is one of many possible approaches to this topic, namely, a terrestrial geological one. This is, however, adequate because the original identification, naming, and documentation of the Younger Dryas event was carried out by Scandinavian Quaternary terrestrial geologists and paleobotanists. In addition, the Younger Dryas is still probably best manifested by an often distinct lithologic change in lacustrine records of Western Europe (Figure 1).

The concept that the late-glacial interval ended with a distinct cold period originates from paleobotanical and lithostratigraphic studies of Swedish and Danish bog and lake sites (Andersson, 1896; Hartz and Milthers, 1901), such as the Allerød clay pit in Denmark (Hartz and Milthers, 1901). The term 'Dryas' refers to the occasionally abundant finds of *Dryas octopetala* (Mountain Avens) leaves in these often minerogenic-rich lake sediments. The prefix 'Younger' stems from the insight that the original 'Dryas' period was preceded by a warmer stage (Allerød), which in turn was underlain by sediments implying at least another cold period (Hartz and Milthers, 1901). With the onset of pollen analysis in 1916, the later refining of pollen analytical techniques, and a steadily growing number of pollen diagrams, it was obvious that the Younger Dryas represented a distinct vegetational setback in large parts of Europe, and during a time when a general glacial–interglacial plant succession and immigration took place. It was generally interpreted as an effect of a sudden decrease in (annual) temperature, unfavorable for the previously rapidly spreading forest vegetation. The cooling favored the expansion of cold-tolerant, light-demanding plants, and led to glacial advances and a lowering of the equilibrium-line altitude. This is clearly documented in, for example, Norway, Sweden, and Finland by the Ra-Middle Swedish endmoraines–Salpausselkä moraine system, by glacier advances in the Alps, and reglaciation in ice-free areas such as the northern British Isles, Faroe Islands, and southern Sweden.

When carbon-14 (^{14}C) dating became a general dating tool, two of the Dryas periods, the Older and Younger Dryas, were designated Nordic late-glacial chronozones (Mangerud et al., 1974), while the cold period preceding the first late-glacial warming and the Bølling Chronozone was often referred to as the Oldest Dryas stadial. Based on a set of Scandinavian ^{14}C records, the age of the Younger Dryas Chronozone was set to 11 000–10 000 ^{14}C years before the present (BP). However, this Nordic nomenclature was soon to become globally used, although the rather detailed climatostratigraphy upon which it was based, was at that time rarely found outside Europe. The research history of the late-glacial zones/periods is summarized by Björck et al. (1998), who also suggested that the often inconsistent stratigraphic nomenclature of the late-glacial

oscillations, including Younger Dryas, should be termed events and be defined by the Greenland Summit ice core stratigraphies. In this new scheme, the Younger Dryas corresponds to Greenland Stadial 1 (GS-1), and the original Allerød warm period is defined as three events: Greenland Interstadial-1c to 1a (GI-1c to GI-1a).

Although the Younger Dryas oscillation had been a well-known feature among European Quaternary geologists for almost a century, it was not until it was 'discovered' on the North American continent that it became a really 'hot' research topic. In spite of reports published at least half a century ago of complex sediment lithologies in eastern Canada and distinct pollen stratigraphic changes in New England in the late-glacial age, these findings were not regarded as evidence for climatic oscillations. However, in the mid-1980s, researchers began to relate these phenomena to a Younger Dryas cooling; old sites were reinterpreted in New England (Peteet, 1987) and in eastern Canada (Mott et al., 1986), and new sites with a presumed Younger Dryas oscillation were found (summarized by Wright, 1989). Mainly based on marine evidence, Ruddiman and McIntyre (1981) presented a model for oceanic Polar Front shifts during the last deglaciation, in which the Polar Front was displaced far south (northern Spain) in the North Atlantic about the same time as when the Younger Dryas cooling in mainland Europe was presumed to have occurred. The implication was that a large part of the North Atlantic, and thus most of the European Atlantic coasts, was shut off from warm Atlantic waters and that the marine environment north of the front was characterized by abundant icebergs and sea ice. The lack of Younger Dryas records in North America probably prevented the authors from drawing the position of the front all the way to the east coast of America. The Ruddiman–McIntyre model of Polar Front shifts and Boyle and Keigwin's (1987) results from the Bermuda Rise showing reduced North Atlantic deep water (NADW) formation during the Younger Dryas played an important role in the increased understanding of the late-glacial climatic shifts, especially, perhaps, of some of the characteristics of, and mechanisms behind, the Younger Dryas cooling.

In the late 1980s, the evidence for a circum-North Atlantic Younger Dryas cooling became more widely accepted, and the common late-glacial climatic pattern around the North Atlantic was clearly manifested by the regional summaries of the North Atlantic Seaboard Programme (NASP) of International Geological Correlation Programme project 253 as well as by the NASP synthesis (Lowe et al., 1994).

The Northern Hemisphere Younger Dryas

With the overwhelming evidence of an amphi-North Atlantic Younger Dryas cooling, it became clear that it must have had an impact over large regions, perhaps even a hemispheric or

Figure 1 A section in a peat bog in Schleswig-Holstein, northern Germany, dug out by Hartmut Usinger in Kiel. The thick light gray unit is a lacustrine sediment, clay gyttja, formed during the Younger Dryas oscillation. The dark unit below is an organic-rich sediment formed during the Bølling-Allerød warm period (GS-1), and the unit above is Holocene gyttja and peat. Note the distinct lower and upper boundaries of Younger Dryas, and for scaling the spade in foreground.

global influence (Broecker, 1994). Its strong impact on North Atlantic trade-wind intensity and regional precipitation patterns shown in the Cariaco basin of the tropical North Atlantic (Hughen et al., 1996) was a clear indication of its large influence on Northern Hemisphere climate.

Possible Triggering Mechanisms Behind the Younger Dryas

Changes in NADW and thermohaline circulation (THC) were excellent mechanisms for explaining the late-glacial climatic oscillations (Boyle and Keigwin, 1987), most clearly displayed in north-west European records where the North Atlantic current has its strongest impact. However, the exceptionally long and severe Younger Dryas cooling, compared with other late-glacial North Atlantic coolings (Björck et al., 1996), led to a special interest in its underlying mechanisms. The idea that a sudden fresh-water event triggered the onset of Younger Dryas, such as the diversion of the outlet of Lake Agassiz from the Gulf of Mexico to an eastern outlet with a more or less catastrophic drainage through the St. Lawrence River (Broecker et al., 1988) and a simultaneous Baltic Ice Lake drainage (Björck et al., 1996) into the North Sea, is a mechanism that is supported by coupled atmosphere-ocean modeling (Manabe and Stouffer, 1988). A sudden decrease in salinity in areas where NADW normally occurs would have a rapid and disturbing effect on the THC. This would seriously hamper the northward meridional heat advection, and this model of explaining the sudden onset and exceptional length of the Younger Dryas has been widely acknowledged as the most plausible mechanism for

the onset of the oscillation. The problem is, however, that it is only based on circumstantial evidence; unless we can pinpoint the onset of such events to the very same year, the link remains indirect. Furthermore, the Younger Dryas Lake Agassiz drainage through the Great Lakes has recently been questioned (Teller et al., 2005), but the last words on this topic are certainly not written.

Timing of the Younger Dryas

The occurrence of a cold oscillation preceding the warm Holocene in all the deep Greenland ice cores, starting with the Camp Century core (Johnsen et al., 1972), became a strong support for those who claimed that Younger Dryas was a significant climatic oscillation. The Greenland Summit ice cores Greenland Ice Sheet Project-2 and Greenland Ice Core Project (GRIP) imply that the Younger Dryas lasted 1150–1300 years, depending on the ice core that was used for the determination (Alley, 2000), and that it started around 12 800 ice years BP. Likewise, the age of the end of the Younger Dryas varies between different Greenland ice cores and their different age models. However, the most likely age seems to be 11 600–11 650 cal. years BP, and it appears to have been synchronous over large parts of the North Atlantic region (Björck et al., 1996; Hughen et al., 1996).

The suggested ^{14}C age of 11 000–10 000 years BP for the Younger Dryas Chronozone (Mangerud et al., 1974) also meant that this ^{14}C age usually was assigned to the climatic oscillation. However, with the advent of ^{14}C accelerator mass spectrometry (AMS) dating during the early 1980s it became possible to ^{14}C date very small quantities (a few milligrams) of well-defined terrestrial organic material (e.g., leaves and seeds) formed in direct contact with atmospheric carbon dioxide. Previously, the normal type of dated material consisted of bulk sediment material, prone to different dating problems such as hard-water errors and reworked organic material. With the increasing number of geologically ‘more reliable’ AMS ^{14}C measurements, it became clear that atmospheric ^{14}C variations were considerable during the millennia preceding the Holocene. In combination with the idea that the late-glacial oscillations were triggered by a varying strength of the North Atlantic THC, and thus by changes in ocean ventilation, these ^{14}C variations were often interpreted as responses within the carbon cycle of atmosphere-ocean exchange processes. For example, during the early 1990s, an increasing number of high-resolution ^{14}C dates around the Allerød-Younger Dryas boundary began to indicate that this often distinct paleoclimatic change was difficult to ^{14}C date in detail; depending on the side of the boundary the ^{14}C samples originated from, ages could vary between 11 000 and 10 600 ^{14}C years BP. Studies also showed that a ^{14}C age of 11 000 years BP clearly predates the boundary, and that the first (oldest) Younger Dryas ^{14}C samples often obtain ages of 10 700–10 600 ^{14}C years BP (Björck et al., 1996). In fact, this very rapid age shift, which we today know is a robust feature, could be used to answer different questions and hypotheses about Younger Dryas. Was this distinct rise in atmospheric ^{14}C content ($\Delta^{14}\text{C}$ values) an effect of a severe disturbance in the North Atlantic THC resulting in decreased (25–50%) ventilation between the ocean and the atmosphere? If this was the case it could, for example, imply that the onset of Younger Dryas was characterized by a

rapid spread of sea ice. In addition, the large ^{14}C changes at this boundary are an excellent time marker for evaluating if the event is hemispherically and/or globally synchronous.

Although the end of the Younger Dryas was pragmatically set to 10000 ^{14}C years BP in the Nordic chronostratigraphy (Mangerud et al., 1974), the majority of age estimates for the end of the climatic cooling, often based on bulk sediment dates, was usually centered around 10200 ^{14}C years BP. However, with the possibility of AMS dating of identified macrofossils, it gradually became clear that the Younger Dryas–Preboreal transition around the North Atlantic was characterized by a so-called ^{14}C plateau (Ammann and Lotter, 1989), that is, a long period when ^{14}C ages are roughly the same, resulting in declining $\Delta^{14}\text{C}$ values. The new calibration curve (Reimer et al., 2004), with the end of Younger Dryas at 11650–11600 cal. years BP, shows that the last 200 years of Younger Dryas are characterized by a gradual decline in ^{14}C ages from 10200 to 10050 ^{14}C years BP (Figure 2). At the transition, a 200–250-year long ^{14}C plateau starts, with ^{14}C ages varying between 10050 and 10000 ^{14}C years BP; thus a ^{14}C age of 10000–10050 for the end of Younger Dryas is presently the best estimate. The boundary now seems to coincide approximately with the onset of a ^{14}C plateau, implying an increased global ocean ventilation rate; that is, if carbon cycle changes, and not ^{14}C production, are responsible for this decrease in $\Delta^{14}\text{C}$.

We can conclude that the Younger Dryas cool event is bordered by distinct changes in the atmospheric ^{14}C content. By comparisons with the beryllium-10 (^{10}Be) record from ice cores, it shows that the main part of these changes cannot be

Figure 2 Part of the radiocarbon calibration data set IntCal04 (Reimer et al., 2004), based on radiocarbon-dated tree rings from German pines, between 10500 and 9500 ^{14}C years BP. Each thin vertical line on the curve shows a ^{14}C age of a dated tree ring, and the length of the line is the ^{14}C dating error (1σ). The calibration curve is compared to a set of 20 ^{14}C dates on terrestrial macrofossils from sediments in three south Swedish lakes (Björck et al., 1996). The blue dates come from sediments formed just or slightly before the Younger Dryas–Holocene boundary, and the red dates are from sediments of very early Holocene age. The vertical lines display the radiocarbon error (1σ) and the horizontal lines show the calibration error (1σ). The dashed lines mark the 10050–10000 ^{14}C years plateau.

ascribed to production changes, but must be related to variations within the carbon cycle. Because of the large and sudden changes, it is very likely that the largest carbon reservoir – the ocean – was a key player for these variations. This is an additional indication that the Younger Dryas cooling was triggered by THC changes and a varying strength of NADW.

Younger Dryas Records Outside the Amphi-North Atlantic Region

In considering evidence for a Northern Hemisphere Younger Dryas oscillation it is necessary to focus on the huge North Pacific region. Several studies in this region have shown that climate variability during the last ice-age cycle seems to have been very similar to that reconstructed from terrestrial, ice core, and marine records in the circum-North Atlantic region. These studies constitute marine and lacustrine sediments, speleothems, and loess profiles, ranging from the west coast of North America/Central America to Japan and up onto the Chinese loess plateau. Although the chronologies for some of these records have often been too poor for direct correlations to the often better dated North Atlantic records, the climatic pattern seems very similar. It has, therefore, often been stated that a direct link exists between North Atlantic and North Pacific climates on millennial time scales. In fact, a Younger Dryas-like event seems to be the last of these glacial suborbital climate oscillations in the North Pacific region, but the exact timing has usually not been possible to determine. Although not very well dated, one of the first indications of a Younger Dryas event in the north-eastern Pacific region came from a lacustrine study in south-eastern Alaska (Engstrom et al., 1990), showing a pine parkland being replaced by tundra. However, the climatic ‘signature’ of this event is often very different on both sides of the North Pacific. While the Santa Barbara basin sediments became bioturbated (Kennett and Ingram, 1995) as an effect of locally increased ventilation, the Japan Sea records show a change to laminated sediments, possibly caused by increased sea ice cover/anoxic conditions. The Chinese speleothems and loess profiles suggest an oscillating strength of the East Asian monsoon system during the Last Termination, with a weakening of the Younger Dryas summer monsoon, explaining the more arid conditions during this time, and a strengthening of the winter monsoon with the increased dust load from central Asia. The latter is seen in the Greenland Summit ice cores. Uranium–thorium ages from Tangshan Cave in east China (Zhao et al., 2003) constrain the Younger Dryas fairly well (12500–11540 years BP), but indicate that the onset and end of the Younger Dryas dry event in East Asia may have been delayed in relation to the North Atlantic. There are, however, other less well-dated records in the desert–loess boundary area of northern China, implying more oscillating Younger Dryas conditions with tropical–polar interconnections (Zhou et al., 2001). At Lake Suigetsu in Japan (Nakagawa et al., 2003), the Last Termination in East Asia has probably been studied in the greatest detail. Its annually laminated sediments have been ^{14}C dated and pollen analyzed, and its pollen record has been quantified in terms of mean annual temperature. The reconstruction shows a temperature decline of 2–4 °C between 12300 and 11250 years BP, based on the varve chronology, which implies a substantial delay at

the onset and end of the Younger Dryas in relation to the North Atlantic.

The atmospheric ^{14}C signal is a global signal, with a few decades of lag for the Southern Hemisphere. It is therefore of interest to compare the set of ^{14}C dates at the onset and end of the Younger Dryas in Lake Suigetsu with corresponding ^{14}C dates in the North Atlantic region. As noted above, the very onset of the Younger Dryas is dated to 10 700–10 600 ^{14}C years BP on terrestrial macrofossils and tree rings in Europe, after a shift from ca. 11 000 ^{14}C years BP in less than 50 cal. years. The same shift is seen in the Lake Suigetsu ^{14}C record, but it predates Lake Suigetsu's Younger Dryas by a few hundred years. The Chinese and Japanese data, therefore, confirm each other: the Younger Dryas dry and cold event in East Asia lags the North Atlantic Younger Dryas cooling with at least 200–300 years. It is probable that the reason behind this may lie in the often suggested 'winter dominance' of the Younger Dryas climate, creatively evaluated and reviewed by (Denton et al., 2005). Studies show that late-lasting Eurasian snow cover will hamper the following summer monsoon by cooling down the land mass, decreasing the monsoon driving temperature gradient between the sea and the continent. The several hundred year-long transition into Younger Dryas, in Chinese and Japanese records, could imply that the Younger Dryas cold winter conditions in the North Atlantic region spread eastwards on the Eurasian continent resulting in gradually longer and cooler winters, increasing the intensity of the winter monsoon and gradually weakening the summer monsoon.

Similarly, if we compare the ^{14}C ages at the end of the Younger Dryas in Lake Suigetsu with the ^{14}C ages of the Younger Dryas–Preboreal transition around the North Atlantic and around 11 600 cal. years BP in the calibration data set, we can try to evaluate lags between the records. In European detailed ^{14}C records, for example (Björck et al., 1996), Late Younger Dryas ^{14}C ages are greater than 10 000 years BP and rather around 10 100 cal. years BP, while the early Preboreal ^{14}C ages are usually not older than 10 100 years BP (including 1σ), but rather around 10 000 years BP (Figure 2), a pattern which can be seen in the calibration data set before and after 11 600 cal. years BP. Because of the fairly large spread of the Lake Suigetsu ^{14}C dates at this time period a similar distinct pattern is hard to detect. However, it is impossible to shift the ^{14}C dates of the transition in Lake Suigetsu to more than 100–200 varve years older ages, and therefore the notion of a delay of the Holocene warming in Japan, and perhaps also in other parts of East Asia, seems very likely. The scenario may be the same as for the delayed onset of the Younger Dryas; the Eurasian continent was gradually warmed from the west and the propagation of the marine warming from the North Atlantic into the Pacific Ocean took a few centuries.

The presence of a Younger Dryas-like oscillation in the circum-North Atlantic and circum-North Pacific regions would imply that it also occurs in the region in between: North Africa and the Arabian Sea/northern Indian Ocean. Independent data sets show that northern equatorial Africa was dominated by arid conditions during the time of the Younger Dryas: lake levels fell in the west and east (Gasse, 2000), and mountain forests were reduced. These mostly arid conditions may have been related to decreased intensity of the summer monsoon, which is supported by evidence of decreased summer

upwelling along the Oman and Pakistan coasts during the Younger Dryas; summer upwelling strength is closely linked to the regional summer monsoon.

It is clear that the partial reorganization of the climate system during the Younger Dryas had a fairly substantial impact on the Northern Hemisphere climate, especially the winter conditions; both the atmospheric and marine circulation pattern changed, North Atlantic sea ice extended considerably, the albedo increased, monsoon intensity decreased, and atmospheric aerosols became more abundant, possibly most so in winter.

Is There Evidence for a Younger Dryas Oscillation in the Southern Hemisphere?

Although the Younger Dryas was most likely triggered by changes in the North Atlantic, it would be surprising if this event was not felt by the climate system of the Southern Hemisphere; the large impact of the Younger Dryas on the Northern Hemisphere climate ought to have been propagated, in one way or another, into some of the driving mechanisms for the Southern Hemisphere climate system.

South America is probably the continent where discussions about the presence or absence of a Younger Dryas cold event have been most lively. Most of these conflicting glacial, palynological, and paleoentomological records are from Chile and Argentina, but several records also exist from more northerly areas such as the central Andes and in the Amazon Basin (Clapperton, 1993). Paleoclimatic interpretations of these data sets and the chronology of the records seem to have been the two main obstacles for finding a common Younger Dryas signal. The hitherto best dated series of South American cooling events come from two sites at 41°S in Chile and Argentina (Hajdas et al., 2003) dated to ca. 11 500–10 200 ^{14}C years BP (ca. 13 400–12 000 cal. years BP). This implies that any South American equivalent to the Younger Dryas overlapped half of the European Allerød warm period and half of the Younger Dryas cooling. It should, however, also be remembered that the data sets analyzed and discussed, were formed during a climatically very dynamic time period. Large differences should, therefore, be expected between the Amazon Basin at the Equator and Tierra del Fuego in the south, the Atlantic coast in the east, and the high Andes in the west. The debate was also fueled by reports of well-dated so-called Younger Dryas glacial advances in New Zealand (Denton and Hendsy, 1994) with mean ^{14}C ages of 11 000 ^{14}C years BP. In light of the already existing knowledge that such ages predate the North Atlantic Younger Dryas cooling, it would have been more appropriate to regard these dates as evidence for 'Allerød glacial advances in the Southern Hemisphere.' Time is also needed to build-up glacier ice and form the moraines. The concept of pre-Younger Dryas glacial advances in New Zealand is now generally accepted (Shulmeister et al., 2005), and detailed dating of a climate reversal in Kaipo bog, with an age of 13 600–12 600 cal. years BP (Hajdas et al., 2006), shows that this cooling most likely triggered any glacial advances.

Since the 1980s, there have been indications that Antarctic ice cores show a cold spell, the Antarctic cold reversal (ACR), before the onset of the Holocene. However, the exact timing of this event has been uncertain due to difficulties with obtaining

sufficiently detailed chronologies for Antarctic ice cores. It was regarded by many as a strong indication for an Antarctic Younger Dryas and, as such, also a Southern Hemisphere one. However, when very detailed methane (CH_4) measurements of GRIP and the Antarctic Vostok and Byrd ice cores were produced (Blunier et al., 1997), it became obvious that Antarctic and Greenland climatic changes are asynchronous, especially during glacial times (Blunier et al., 1998). With respect to the comparison between the ACR and the Younger Dryas, the CH_4 correlations have shown that the ACR began around 13 800 ice years BP and ended at ca. 12 200 ice years BP in the Vostok ice core (Petit et al., 1999). Furthermore, the post-ACR rise in temperature occurred over ca. 600 years. This implies that the ACR started ca. 1000 years before the Younger Dryas started in the Northern Hemisphere, that is, at the beginning of the Allerød warming (GI-1c), and ended in the middle of the Younger Dryas (Figure 3). In fact, this type of climatic development seems consistent with many other observations in the Southern Hemisphere, such as the New Zealand climatic reversal/glacial advances, marine cores in the South Atlantic and Indian Ocean, and records south of the equator on the Atlantic side of Africa (Gasse, 2000). However, the Antarctic ice cores do not give us a completely consistent picture; the isotope stratigraphy of the Last Termination from the Taylor Dome ice core is more similar to the Greenland ice cores than are the other Antarctic cores (Steig et al., 1998). A warming peak is reached at ca. 14 000 ice years BP, which seems to be a normal feature in Antarctic ice cores, followed by a gradual cooling with minimum values at 12 900–12 300 ice years BP, corresponding chronologically to the first part of the Younger Dryas. At ca. 11 500 ice years BP a sudden Holocene warming occurred, which is in contrast to the long transition seen in the Vostok ice core. It should, however, be pointed out that these time differences may partly be explained by problems in the various ice chronologies. It is also possible that

different regions of Antarctica responded in different ways to the deglacial warming of the Last Termination. Most of the currently available data do, however, imply that the ACR began more than 1000 years before the onset of the Younger Dryas in the north, but not in direct 'antiphase' with the Bølling–Allerød (GI-1) warming in the north. They also imply that the start of the Holocene warming in most Antarctic ice cores leads the warming in the north with by at least 500 years.

The findings that warmings during glacial time in Antarctic ice cores roughly coincide with cold periods over the Greenland Summit, and vice versa, resulted in the hypothesis of a bipolar seesaw climate pattern (Broecker, 1998). To what degree the Younger Dryas and the ACR are part of this is difficult to judge, at least as long as the chronologies are incomplete. Even before this hypothesis was formulated, climate models had shown that a breakdown of the THC in the North Atlantic would result in a warming of the Southern Ocean. Later models differed on how much such a warming would spread in the Southern Hemisphere: to the entire hemisphere or only to the South Atlantic and southern Indian Ocean? Based on today's knowledge it is, however, tempting to conclude that (partial) breakdown of THC and NADW in the North Atlantic, as a result of sudden fresh-water discharges, resulted in a more or less extensive warming during Younger Dryas time in the Southern Hemisphere. In fact, it is also likely that large parts of the Southern Hemisphere experienced a cold period (ACR) before its entry into the Holocene warming, but clearly before the Northern Hemisphere Younger Dryas.

Conclusions

We can conclude that the present interglacial, the Holocene, was preceded by a distinct cool/dry event in the Northern

Figure 3 The GRIP oxygen isotope data (Johnsen et al., 2001) displaying temperature shifts over the Greenland Summit compared with the relative temperature record from the Vostok station in Antarctica (Petit et al., 1999), between 20 000 and 10 000 ice years BP. Ice years are approximately the same as calendar years. The positions of the Younger Dryas and the ACR are indicated. Note that the timescale of the GRIP data around Younger Dryas time is about 100 years too young when compared with the latest, but still unpublished chronology from the NorthGRIP core.

Hemisphere, generally designated the Younger Dryas cooling or the GS-1 event in the Greenland ice cores and dated to ca. 12 800–11 600 cal. years BP, and manifested by a winter-dominated climatic signature. In East Asia, there is good evidence that the onset and end of the event was slightly delayed in relation to its North Atlantic counterpart. It is likely that the event was triggered by rapid melt-water outbursts into the North Atlantic from the Laurentide and Fennoscandian ice sheets.

In large parts of the Southern Hemisphere there is clear evidence of a pre-Holocene cooling event. The timing and character of this event are, however, less clear. Most data indicate that it began 500–1000 years before its Northern Hemisphere equivalent and ended at least 400 years before its termination around the North Atlantic. This means that it overlaps most, or at least the later part, of the Allerød warm period (GI-1c–1a) and at least the beginning of the Younger Dryas (GS-1) in the north. It also shows that the Holocene warming began much earlier in the Southern Hemisphere, during the peak of the northern Younger Dryas cooling. It is difficult to judge to what extent this pattern is part of a bipolar seesaw, but the transitional overlap between northern–southern warming and cooling ([Figure 3](#)) is reminiscent of the interhemispheric phase lags during the Dansgaard/Oeschger cycles of glacial time. A key question is of course: which hemisphere leads? With respect to the Younger Dryas oscillation, it is likely that a partial shutdown of the Atlantic conveyor belt decreased northern THC, which led to a warming in the Southern Ocean, explaining the early onset of the interglacial warming in the south. If we postulate that fresh-water forcing in one hemisphere is the main forcing mechanism for warmings in the other hemisphere, the Northern Hemisphere Heinrich-1 event could have triggered the onset of warming in Antarctica at 17 000 ice years BP, and if melt-water peak-1A originated from Antarctica ([Clark et al., 1996](#)), it would imply that it triggered the Bølling warming ([Weaver et al., 2003](#)). Thus, the bipolar seesaw pattern may be very complex, especially during phases of deglaciation, and the Younger Dryas oscillation is certainly an important and globally significant part of the complexities of the Last Termination.

The Last Millennium

The period of roughly the last millennium is particularly important for characterizing the natural variability of the climate and, in so doing, framing possible, more recent anthropogenic climate changes. Numerous natural archives or ‘proxy’ records, such as tree rings, corals, ice cores, lake sediments, and historical documents, are available to aid in reconstructing the details of climate changes within this time frame (Bradley, 1999; Bradley and Jones, 1995; Fritts, 1976; Huang et al., 2000; Jacoby and D’Arrigo, 1989; Jones and Mann, 2004; Jones et al., 2001; Luterbacher et al., 2004; Mann et al., 1998; Wigley et al., 1981). Moreover, the basic external constraints on the climate system (the configuration of the continents, the extent of any continental ice sheets, and the geometry of Earth’s orbit) have not changed appreciably on the millennial timescale. For this reason, the variability of the climate over the period of the past one or two millennia, but prior to the past two centuries during which anthropogenic impacts are likely to be a dominant factor, can provide insights into the envelope of natural variability of the climate. These insights can, in turn, guide our assessment of the extent to which recent climate changes are anomalous and the extent to which these changes are likely related to nonnatural (i.e., anthropogenic) impacts on climate.

A considerable body of scientific research in recent decades has sought to characterize the nature of climate variability over the past millennium (Bradley and Jones, 1995; Briffa et al., 2001). Numerous groups have used proxy data to reconstruct this history of large-scale changes in temperature, precipitation and drought, and atmospheric circulation in past centuries. These reconstructions place in a richer and significantly more detailed context previous notions of climate change embodied by terms such as the ‘Little Ice Age’ and ‘Medieval Warm Period.’ In particular, much of the climate variation in past centuries is characterized by a complex pattern of regional and seasonal variation that is difficult to describe using simple, broad labels. Some of the past observed changes appear to be consistent with changes in radiative forcing of climate (e.g., due to the radiative impacts of explosive volcanic eruptions and inferred changes in solar output), whereas other changes are probably associated with internal, chaotic oscillations of the climate system. At hemispheric or global scales, late twentieth-century climate changes appear to be anomalous in the context of at least the past millennium. Simulations with theoretical climate models support the conclusion that these changes are likely associated, in large part, with anthropogenic impacts on the climate.

Large-Scale Temperature Trends

Numerous research groups have used networks of climate proxy data to reconstruct large-scale surface temperatures in past centuries at seasonal and annual resolution. These reconstructions emphasize both spatial patterns of past temperature

change and average changes over the globe and both hemispheres. Due to the greater number of available climate proxy data (Figure 1), these reconstructions have generally emphasized temperature changes in the Northern Hemisphere and over a period extending as far back in time as the past two millennia (Jones and Mann, 2004; Moberg et al., 2005; Oerlemans, 2005; Rutherford et al., 2005). Most reconstructions indicate generally cooler conditions during the fifteenth through nineteenth centuries, which includes the intervals usually used to define the Little Ice Age. Warmer conditions are found during the eleventh through the fourteenth centuries, which includes the intervals typically used to define the so-called Medieval Warm Period (Folland et al., 2001).

The reconstructions suggest anomalous late twentieth-century warmth at hemispheric scales (Figure 2). Uncertainties are greater, due to the paucity of Southern Hemisphere proxy data, for the Southern Hemisphere and globe, but it is also likely that the late twentieth-century warmth is unprecedented in these contexts as well (Jones and Mann, 2004). These observations are consistent with evidence that radiative forcing has been considerably enhanced by anthropogenic influences during the twentieth century.

Regional Climate Changes

Surface Temperature

In interpreting past temperature changes, one must carefully distinguish regional temperature changes from large-scale, global, or hemispheric average temperature changes. Large-scale average temperature estimates must be based on the average of temperature estimates over a sufficiently large number of distinct regions and on a contemporaneous basis. Drawing conclusions from any one or small set of regions at any particular time is perilous because relative temperature variations on interannual, decadal, and even millennial timescales are often quite different (Mann et al., 2003). Temperature variations in continental regions are often substantially greater than those in oceanic regions, and they are often different during different seasons (e.g., summer vs. winter). Indeed, relative temperature changes are often observed to be opposite in different locations. This behavior is believed to be due to a number of factors, including long-term changes in the characteristics of the prevailing atmospheric and oceanic circulation. Cyclonic storm systems, for example, typically cause regions in one sector of the storm to warm while causing regions in other sectors of the storm to cool. Increases in the strength of a warm poleward ocean current lead to warming in higher latitude regions at the expense of cooling in lower latitude regions. Moreover, changes over time in these behaviors of the ocean and atmosphere are typically regional, rather than global, in their influence.

Figure 1 Map of available high-resolution (annual or decadal) temperature proxy indicators available over much of the past two millennia. The boxes represent the individual locations used in series that represent regional composites. Figure 2 Reconstructions of northern annual temperatures over the past millennium. Shown for comparison is the instrumental Northern Hemisphere record 1856–2003. Also shown is the 95% uncertainty band (shading) for one of the reconstructions. Adapted from Jones PD and Mann ME (2004) *Climate over past millennia*. *Reviews of Geophysics* 42: RG2002.

Considerable spatial variability is observed in the temperature variations over the past millennium. Although the Little Ice Age is observed to have been a relatively cool period for certain regions such as Europe, it clearly was not uniformly cold for all regions. Similarly, the so-called Medieval Warm Period of the ninth through the thirteenth centuries was in fact a cold interval for many regions, despite the fact that it was a warm period for Europe. The notions of the Little Ice Age and Medieval Warm Period as global climate episodes is, to some extent, an artifact of the Eurocentric origins of these terms. Although relative hemispheric warmth during the tenth through the twelfth centuries and cool conditions during the fifteenth through the early twentieth century are indeed evident for hemispheric mean temperature (Figure 1), the changes are small (only a few tenths of a degree C) compared to the larger regional changes (often a degree or more). The specific periods of coldness and warmth differ from region to

region (Figure 3) from those for the Northern Hemisphere as a whole. Temperature changes appear to have been different for continents and oceans and for different seasons. The greatest episodes of cooling during the seventeenth through the nineteenth centuries appear to have occurred over the continents and during summer. Studies suggest that this may be related to the influence of explosive volcanism on climate.

Precipitation and Drought

Changes in hydrological climate variables such as precipitation and drought are equally, if not more, important from a societal standpoint than are past changes in surface temperature. A considerable body of recent work has sought to use paleoclimate proxy indicators, such as tree rings, corals, ice cores, and lake sediments, combined with long historical documentary evidence to document these past changes.

Figure 3 Temporal histories of nine temperature-sensitive proxy records, chosen to illustrate a variety of proxy types, regions, and seasonal windows. All series have been smoothed with a 40-year low-pass filter, then normalized so that the filtered series have unit standard deviation. Reproduced from Mann ME, Ammann CM, Bradley RS, et al. (2003) On past temperatures and anomalous late 20th century warmth. *EOS* 84: 256–258. Copyright AGU.

Much of this work has emphasized changes in North American drought patterns in past centuries. Tree-ring reconstructions suggest that the range of North American drought variability observed during the twentieth century may not fully represent the range of drought evident in earlier centuries. The reconstructions also suggest that the twentieth-century dust bowl still stands out as the most extreme summer drought in large areas of the United States in recent centuries. A sixteenth-century ‘megadrought’ appears to have been important over the United States, western Canada, and northwestern Mexico and may have far exceeded the twentieth-century dust bowl event in scale and magnitude. For the western United States on the whole (Cook et al., 2004), the earlier centuries of the past millennium were relatively dry and later centuries relatively wet (Figure 4). Reconstructed lake levels in equatorial east Africa (Kenya) suggest a similar pattern of dry conditions during the earlier part of the millennium (eleventh through thirteenth centuries) and wet conditions during the later centuries (e.g., fourteenth through nineteenth centuries), with peak wet conditions during the mid-seventeenth to the mid-eighteenth centuries (Verschuren et al., 2000). These long-term changes in drought may be tied to changes in the El Niño/Southern Oscillation (ENSO) phenomenon, as discussed in more detail later. The long-term reconstructions suggest that drought in the western United State during the past decade may be approaching in magnitude the most severe droughts of the past millennium.

Changes in precipitation patterns in Europe in past centuries, including dry conditions in central Europe and the European Alps during the late seventeenth and early eighteenth centuries, may reflect changes in the large-scale atmospheric circulation (e.g., the North Atlantic Oscillation or ‘NAO’ phenomenon) influencing the region. Independent support for this conclusion is obtained from the pattern of mountain glacier expansion and retreat in both northern and southern Europe in past centuries.

Changes in Atmospheric and Oceanic Circulation

At regional scales, climate variability and change in past centuries is closely associated with the behavior of particular modes of climate variability, such as NAO and ENSO. These modes describe the characteristic patterns of reorganization of the atmospheric and oceanic circulations over time. Changes in NAO and ENSO are especially relevant for understanding the complex patterns of climate change associated with the so-called Little Ice Age and Medieval Warm Period.

Proxy climate indicators do not directly measure past changes in atmospheric circulation. Nonetheless, proxy measures of past temperature and precipitation changes are often used to indirectly infer past changes in atmospheric circulation and climate indices.

El Niño/Southern Oscillation

Indices of ENSO such as the Southern Oscillation Index (Figure 5) have been reconstructed based on tree rings in ENSO-sensitive regions and coral data from the tropical Pacific Ocean (Evans et al., 2002; Stahle et al., 1998). In addition, qualitative evidence regarding the history of El Niño events in past centuries is available from long-term historical documents in regions influenced by El Niño (e.g., tropical South America). The various reconstructions show important features in common. The large 1982–83 and 1997–98 El Niño events, for example, seem to be outside the range of variation seen over the past few centuries. The uncertainties in the reconstructions are still substantial. A more extensive network of ENSO-sensitive proxy indicators will likely be required for more confident conclusions regarding the behavior of ENSO in past centuries.

Fossil coral evidence, although incomplete, allows insights into changes in both the interannual variability and the mean state of an ENSO-dominated region of the tropical Pacific over roughly the past millennium (Cobb et al., 2003). Such evidence suggests La Niña-like conditions in the earlier centuries of the past millennium (the tenth through the thirteenth centuries) and El Niño-like conditions later on (e.g., the mid-seventeenth century through the mid-eighteenth century). Such conditions are consistent with the previously discussed evidence for dry and wet conditions, respectively, in equatorial east Africa during these same time intervals. Some studies suggest a relative absence of interannual variability, but a persistence of decadal variability, during the early and mid-nineteenth century. Non-stationarity is evident on multidecadal timescales in the extra-tropical influences of ENSO during past centuries.

North Atlantic Oscillation

A number of studies have sought to reconstruct the boreal winter or cold season NAO (or the related Arctic Oscillation or AO index) in past centuries (Luterbacher et al., 1999). These reconstructions are based on composites of proxy data or combinations of proxy, historical, and instrumental data, calibrated against the modern instrumental NAO index. Most of the NAO reconstructions suggest the trend in recent decades toward an enhanced positive NAO index to be relatively unusual, if not unprecedented, in recent past centuries (see Figure 5). This conclusion seems consistent with insights gained from model studies with regard to both the natural variability of the NAO and the potential response of the NAO to anthropogenic forcing of the climate. As with the reconstruction of El Niño indices discussed previously, sizable uncertainties in the reconstructions still preclude any definitive conclusions. Preliminary reconstructions of the summer AO index have also been attempted. These reconstructions suggest different behavior in past centuries from the winter NAO index.

The NAO pattern of atmospheric variability may have played a prominent role in explaining regional patterns of surface temperature change in past centuries in the extratropical Northern Hemisphere. For example, a tendency toward the negative phase of the NAO seems to explain the enhanced regional winter cooling in Europe during the seventeenth century. Similarly, a tendency toward the positive phase of the NAO may explain the enhanced regional warming in Europe during the medieval times. Such conclusions are consistent with ice borehole data from Greenland and from geochemical and geobiological evidence from North Atlantic and Mediterranean sediment cores. Forward modeling of glacial mass balance in Europe in past centuries suggests that the inverse relationship between glacier expansion and recession in northern and southern/central Europe in past centuries is consistent with NAO impacts on winter precipitation. Long-term evidence from ocean and lake sediments suggests that the NAO has played a prominent role in the climate variability of the North Atlantic and neighboring regions over several millennia.

Other Modes

A number of other climate indices have been reconstructed in past centuries from proxy data. These reconstructions are

typically more preliminary, and even more uncertain in nature, than reconstructions of the NAO and ENSO indices. One such index, the Pacific Decadal Oscillation (PDO) index, describes climate variability in the North Pacific over the past several centuries (Minobe, 1997). The behavior of the PDO has been reconstructed from tree-ring data and ice cores from maritime glaciers in the Pacific Northwest of the North American continent. The various reconstructions of this index suggest robust decadal variability over the past several centuries impacting the climate of the North Pacific and the North American continent. In certain cases, the reconstructions indicate a substantial positive trend in the PDO since the mid-nineteenth century.

Another climate index, the Atlantic Multidecadal Oscillation (AMO), describes a roughly 50- to 70-year pattern of variation in sea surface temperature over the North Atlantic Ocean, with larger scale impacts on atmospheric temperature and circulation over a substantial portion of the extratropical Northern Hemisphere. The behavior of this index in past centuries has been reconstructed from a number of different sources of proxy information (Delworth and Mann, 2000). Model simulations produce a mode of variability similar to the observed AMO in both its spatial pattern and its dominant (multidecadal) timescale of variation. The simulations suggest that the origins of the variability are in coupled ocean-atmosphere processes that interact with the thermohaline circulation of the North Atlantic Ocean on multidecadal timescales (Delworth and Mann, 2000). The reconstructions of the AMO indicate substantial multidecadal variability in North Atlantic climate over several centuries. The twentieth-century oscillations of the AMO have been implicated in the irregularity of the pattern of warming in the Northern Hemisphere during the twentieth century and in some changes over time in the frequency and intensity of Atlantic tropical storms and hurricanes.

Reconstructions from proxy data of the Southern Hemisphere counterpart to the AO index, the Antarctic Oscillation index, have also been attempted in recent years. Due to the paucity of high-resolution Southern Hemisphere proxy data, however, such reconstructions are necessarily preliminary and highly uncertain in nature.

Theoretical Modeling Results

A number of simulations of the climate over the past millennium or longer have been performed using a variety of theoretical climate models and empirical estimates of past natural and anthropogenic radiative ‘forcing’ histories. The natural forcing generally includes changes in solar radiative output and dust aerosols due to explosive volcanic forcing, whereas the more recent anthropogenic radiative forcing generally includes a combination of human increases in greenhouse gas concentrations since the eighteenth century and industrial aerosols produced largely during the twentieth century. In some simulations, the more secondary anthropogenic impacts during the nineteenth and twentieth centuries associated with human land use changes are also included. Temperature changes over the past millennium can be diagnosed directly from the simulation output. These theoretical estimates of

Figure 6 Model-based estimates of Northern Hemisphere temperature variations over the past two millennia. Series have been smoothed to highlight variations on timescales greater than 40 years. The simulations employ a range of climate models with differing sensitivities to radiative forcing and employ various different estimates of radiative forcing histories, including natural (solar + volcanic) and modern anthropogenic (greenhouse gas and sulfur aerosol) impacts. Shown for comparison is the instrumental Northern Hemisphere record for 1856–2003 and an empirical proxy-based estimate of Northern Hemisphere mean temperature changes with its 95% uncertainty band (shading). Adapted from Jones PD and Mann ME (2004) *Climate over past millennia. Reviews of Geophysics* 42: RG2002.

past temperature changes are entirely independent of the proxy-based, empirical estimates. Comparisons between the empirical and the modeled temperature histories can thus greatly inform our interpretation of the factors governing the climate changes of the past millennium. Comparisons of the empirical Northern Hemisphere temperature reconstructions with the modeled Northern Hemisphere mean temperature changes (Figure 6) demonstrate that natural factors appear to explain the major reconstructed surface temperature changes of the past millennium, prior to the twentieth century (Crowley, 2000; Robock, 2000).

Only anthropogenic forcing of climate, however, can explain the recent anomalous large-scale warming in the late twentieth century (Crowley, 2000; Crowley et al., 2003). The simulations reproduce the anomalous late twentieth-century hemispheric warmth and indicate that it can only be explained by anthropogenic (greenhouse gas combined with sulfate aerosol) forcing. Moreover, the natural variability produced by the models is generally consistent with the long-term proxy-based reconstructions within published uncertainties. Some simulations overpredict the observed warming since the early to mid-nineteenth century, apparently due to the absence of important forcings (e.g., anthropogenic aerosols or land use changes). These simulations typically appear too cold during the nineteenth century, relative to the instrumental record and the reconstructions, when they are aligned to agree with the instrumental record during the twentieth century (as in Figure 6). Simulations that take into account nineteenth- and twentieth-century land use changes match the observations more closely, suggesting the importance of including land use changes as a significant, albeit secondary, nineteenth- and twentieth-century external radiative forcing. One model simulation ('GKSS'; see Figure 6) suggests especially large-amplitude variations in past centuries, relative to other simulations and reconstructions, but it appears to be highly unrealistic. The larger variability displayed by this simulation appears to result from a combination of a very large assumed solar forcing amplitude and the absence of twentieth-century sulfate aerosol forcing, and an apparent error in the way the model was

initialized. The initialization error leads to a long-term drift in temperature that is unrealistic in nature.

It is in some respects more informative to compare the spatial patterns of the reconstructed and modeled changes rather than just the simple hemispheric means. An analysis of the spatial patterns of past temperature changes, for example, can help elucidate the role of dynamical responses of the climate related to factors such as NAO and ENSO. The substantial cooling in large areas of Europe during the late seventeenth and early eighteenth centuries appears to be related to long-term variations in NAO that are themselves forced by a combination of changes in solar radiative output and explosive volcanism (Figure 7).

These changes are associated with a large-scale dynamical response of the climate system to natural radiative forcing by explosive volcanic activity and solar output that interacts with the NAO pattern of atmospheric circulation. The moderate apparent lowering of solar irradiance during the seventeenth century led to only moderate decreases in the hemispheric mean temperature (see Figure 6). However, seasonally reinforced patterns of response to this forcing, which include substantial continental summer cooling due to the lesser thermal inertia of land relative to ocean and winter cooling over most land regions due to an induced shift toward the negative phase of the NAO, lead to a tendency for strong annual mean cooling in some regions such as Europe (Schmidt et al., 2004; Shindell et al., 2001). Conversely, some land regions (e.g., northeastern North America) are observed to warm due to the changes in atmospheric circulation associated with the negative phase of the NAO that lead to flow of warmer maritime air regions during times of decreased solar irradiance.

Past volcanic forcing leads to larger annual hemispheric mean temperature changes than does past solar forcing due to the substantially greater associated radiative forcing changes. However, in the case of volcanic forcing, a tendency for seasonally opposite direct radiative and dynamical (i.e., NAO) responses leads to offsetting seasonal temperature changes over extratropical continental regions (cooling and warming, respectively), leading to smaller regional annual mean changes

Figure 7 Reconstructed and (bottom) simulated annual average temperature difference between 1660–80 and 1770–90. The reconstructed surface temperatures are based on a multiproxy estimate using tree rings, ice cores, corals, and historical data. Model results are based on the sum of the response in two simulations: one incorporating reconstructed solar irradiance changes during this period and one using volcanic forcing scaled to changes over this time. Reproduced from Schmidt GA, Shindell DT, Miller RL, Mann ME, and Rind D (2004) General circulation modeling of Holocene climate variability. *Quaternary Science Reviews* 23: 2167–2181.

than in the case of solar forcing. The predicted pattern of response by a climate model to the lowering of solar irradiance combined with the response to explosive volcanism matches the empirical, reconstructed pattern of temperature change between the late seventeenth and late eighteenth century (Figure 7). The seasonally opposite responses to volcanic forcing over the extratropical continents explain why some Northern Hemisphere average temperature estimates (Figure 6) emphasizing the summer or warm season and the extratropical continents show greater variation in past centuries than other reconstructions emphasizing the full hemisphere and all seasons.

Recent work suggests that ENSO may also be an important component of the response of the climate to forcing during the past 1000 years. Model simulations using simple models of the coupled tropical ocean–atmosphere to study the response of ENSO to solar and volcanic forcing (Mann et al., 2005) yield results consistent with the proxy evidence for past changes in ENSO discussed previously. The model simulations indicate a counterintuitive tendency toward El Niño (warm eastern and central tropical Pacific) conditions in response to negative radiative forcing (past explosive tropical volcanic eruptions or decreases in solar irradiance) and a tendency for La Niña-like conditions in response to positive radiative forcing (i.e., increases in solar irradiance). This relationship results from the complex pattern of tropical ocean–atmosphere dynamics and feedback responses of ENSO to changes in

radiative forcing. The combined response of ENSO to solar and volcanic forcing in past centuries provides a potential explanation for why the tropical Pacific appears to have been in a cold La Niña-like state during the Medieval Warm Period and a warm El Niño-like state during the Little Ice Age (Adams et al., 2003), as discussed previously. These forced changes in ENSO would likely counteract the larger scale warming and cooling at these times, respectively, leading to smaller changes in global and hemispheric mean temperatures than would otherwise be expected. For this reason, climate models that fail to fully resolve the physics underlying ENSO may not provide a reliable indication of past changes in global or hemispheric temperatures.

Further modeling experiments and model/data comparison focusing on the relationship between past radiative forcing of climate, and the behavior of important dynamical modes of variability such as NAO and ENSO over the past one or more millennia, should increasingly help elucidate the factors that may be responsible for important changes in climate in past centuries.

Introduction

Historical climatology is the branch of climatology that uses written documents to investigate past climate. Such records can include instrumental or noninstrumental weather records. For paleoclimatological purposes, historical documentary sources are most appropriately thought of as weather records that pre-date the establishment of official meteorological networks. Modern observing networks use standardized observation methods and instruments for recording and measuring meteorological variables at defined levels of precision and accuracy. The earliest organized networks date from the late eighteenth century, but it was not until the establishment of international congresses by government-funded meteorological services in 1873 that systematic efforts began to standardize procedures and instrumentation internationally (Fleming, 1990). Historical data are more likely to be derived from nonstandard methods of instrument exposure, highly variable observing practices and definitions of weather terms, and uncalibrated instruments. Climatologists working with historical documents attempt to extend modern records back in time using statistical methods that account for nonstandard methods of instrument exposure, observing practices, and instrumentation (Bradley and Jones, 1995; Jones and Mann, 2004). Only by such procedures can the knowledge of past climate be accurately quantified and compared with current and future observations.

Written records are most abundant for the past millennium and some provide temporal resolution at the subhourly to daily timescales, which are simply unavailable for any other type of proxy weather record. The availability of written sources in both time and place are the ultimate limits to climate history reconstruction from such records. These limitations restrict their contribution to the last 1 ka, although some fragmentary records in parts of the Mediterranean region, the Middle East, and China are over 2-ka old. China holds probably the largest collection of written documents with climate information, but even these records contain significant gaps (Ge et al., 2003). Both European and Chinese archives hold large collections of climate information from about AD 1400, with the European records covering the largest geographical area due to the extensive European colonization of the Americas, Africa, Oceania, and Asia. While other paleoclimate proxy records can provide timescales extending thousands to millions of years in the past, historical documents provide unmatched subannual resolution not possible from other sources. Historical records, along with other proxy records (e.g., tree rings and corals), are used in proxy-based reconstructions of climate (see Section 1.3 of Jones and Mann (2004) for bibliographical references). Historical records from outside of Europe and East Asia are still needed to improve the spatial coverage of data and to provide independent checks on climate models. With the increasing knowledge of large-scale climate features on the interannual to millennial timescales and with the improved computational

and statistical methods, there is greater interest in the long-term variability of intraannual and intraseasonal weather and climate (Klein Tank et al., 2002), including the frequency and intensity of local-scale phenomena and hazards. Historical documents are beginning to assist in answering some of these questions (e.g., Chuine et al., 2004). The impact of climate on human affairs is also an important feature of the written documentary record. Past interactions between climate and society are of great interest as current uncertainties about the direction of future climate have a direct impact on current responses and planning for future climate change.

Potential and Limitations of Historical Documents

The challenge of producing climatically homogeneous instrumental records is well recognized (IPCC, 2001). In the first place, the absence of suitable records is a major reason why most of the longest time series are rarely more than 150 years or so in length. The discontinuous and fragmentary nature of historical records requires careful analysis and calibration. Historical data should not be uncritically merged together to form data sets based on heterogeneous source data that have no consistent definitions of terms, frequency of observation, and nonstandardized instrumentation, exposure, and procedures. Even the construction of a simple index or chronology is sensitive to the methods used in its construction.

Both the quantity and quality of instrumental data decrease in number further back in time. Long series of homogeneous weather records can be produced from the noninstrumental component of these records, such as wind direction and rain/snow days that can be linked with modern instrumental records. However, careful source selection and robust statistical methods are still required to produce a homogeneous time series that is useful for paleoclimate studies. For example, the definition of a 'frost' is highly variable as the term may be based on any number of factors or thresholds. The same is true for rain and snow day counts. Observer sensitivities to various weather phenomena vary between persons and within the lifetime of a single individual. Some long time series were drawn up by nonspecialists who uncritically used multiple source documents of varying quality and/or secondary sources (e.g., see the critical analysis of past El Niño events by Ortleib (2000)). Jones and Mann (2004) provide a very useful discussion of unreliable conclusions about past climate due to poor interpretation of data sources.

The potential of new data sources, particularly the greater geographical coverage offered by ships' logbooks, is great. Many of the most important global, hemispheric, and regional climate signals are strongest, or located mainly, over ocean areas (e.g., the El Niño/Southern Oscillation). Colonial archives contain records from the land areas of the tropics that are only now beginning to be rediscovered. Even data sets

that have received attention in the past, such as the extensive records of the Hudson's Bay Company in Canada, contain many records of past weather that are yet to be studied.

Sources and Repositories of Documentary Materials

Documentary written records that provide information on past climate are incredibly plentiful but reside largely in undigitized form in thousands of locations worldwide. One of the most important tasks for historical climatologists is ascertaining the locations of such records. Government and ecclesiastical bureaucracies are the main source of historical climate data. The large Chinese government bureaus of the past 2.5 ka generated large masses of data concerned with climate impacts on agriculture, particularly drought and floods, heat waves and cold waves, and extreme weather events such as typhoons, snowstorms, and localized severe weather (Ge et al., 2003, 2005). Most of the original accounts are now no longer extant, but the surviving documents hint at the large number of such documents that originally existed. In Europe, ecclesiastical records from the Christian churches are the main source of surviving records of climate for the past 2 ka, although the number of documents is especially small in the first thousand years or so. Parish records and chronicles provide a wealth of information providing direct or indirect information on past climate (Le Roy Ladurie, 1988). From about AD 1500, secular government bureaucracies begin to supplant the Church as the most important sources of weather data. However, proselytizing religious groups remain important sources for some of the earliest instrumental weather records in many parts of the world (e.g., missionary accounts from Africa (Nash and Endfield, 2002) and German Moravian missionaries in Greenland and Labrador (Macpherson, 1987)). Personal diaries and journals, including those of exploring expeditions, are among the most important sources of weather, particularly for the past 300–500 years. Similarly, corporate records such as the Hudson's Bay Company and the English and Dutch East India companies provide the only source of weather data for large areas of Canada and India, respectively, that otherwise would not exist.

Given the large array of sources for historical weather data, all archives, libraries, museums, and other repositories of documents should be considered to potentially hold valuable climate data. Government archives, such as the UK National Archives (formerly the Public Record Office) in London and Archives Nationales in Paris, often are the single largest repositories of government records and are the best single sources for many types of records. There can be no substitute, however, for an exhaustive search of all types of repositories. The large volume of potential records makes interdisciplinary cooperation between climatologists, historians, librarians, and archivists essential for scientific investigations of historical climate. Data search efforts supported by the United Nations such as Archival Climate History Survey (ARCHISS) provide an excellent model for locating such records (Gioda et al., 2003). Many universities and archives have searchable databases that facilitate such research.

Types of Documentary Materials

Any written record may provide direct or indirect weather information. Church chronicles, parish records, government

surveys and other official accounts, estate and farm records, records of crop yields and harvest dates, phenological records, diaries and journals (including those specifically devoted to weather), astronomical observatory records, almanacs, books, travel and explorer accounts, newspapers, legal documents, harbor master records, ship protest records (legal documents absolving a ship's captain from damage sustained in a voyage due to weather or accident) and ship logbooks are examples of historical weather data sources. Some of the most numerous and important documentary materials for historical climatology are reviewed here.

Ships' Logbooks

Weather data from ships are an integral part of historical climate data, since about 70% of the Earth's surface is covered with water, but the retrieval of pre-1850 weather reports is limited to the Maury Abstract Log Collection (US Department of Commerce, 1998), the Climate of the World's Oceans (CLIWOC) project (Herrera et al., 2004), and some small private data sets. Large amounts of both instrumental and noninstrumental data from ships remain to be used in paleoclimate studies.

The ship's logbook is a documentary record that has evolved over time in both its content and appearance. A logbook is a record of all of the activities related to the navigation of a ship and significant events that play a role in the ship's journey. A logbook documents the measurements to determine the ship's location, estimated direction and speed of movement, and those features of the wind, weather, and sea that are needed to estimate a ship's location. A sample logbook is shown in Figure 1.

The amount and type of weather information in a logbook varies depending upon the type of ship (merchant vs. naval), the keeper of the logbook (masters, captains, lieutenants, or other party), its location (usually less detail in port), and when it was kept (generally fewer observations were recorded per day in the seventeenth and early eighteenth centuries than in later years).

Instrumental weather records first appear in widely scattered logbooks in the second half of the eighteenth century, but it is only in the mid-nineteenth century that the frequency of temperature and barometric pressure data increase so as to be very common. Noninstrumental weather records of wind direction, wind force, and prevailing weather conditions are available in virtually every logbook. In the English-speaking maritime world of England and the United States, merchant ships normally ceased making entries in their logbooks during their time in port. Navy ships made observations both at sea and in port. Observations in port ceased only if the ship was taken out of service. For this reason, long time series are most likely to be derived from naval ports and other anchorages continuously in use by naval forces.

Table 1 reveals the evolution of the most frequently used wind force terms in common use in ships of the British Royal Navy from the 1690s through the 1820s. The constantly changing frequency of individual terms, relative to others simultaneously in use, points to the need to carefully document changing practices before attempting to use such data for reconstruction of historical wind records. Each country's navy, as well as merchant ship fleets, has its own variants of terms that evolved as well.

Diaries and Journals

Many private diaries kept by individuals are available from many parts of the world. Some are devoted solely to weather (Figure 2) while others are oriented toward many topics, the weather of which is only one part of the content (Figure 3). The usefulness of diaries and journals for climate research depends upon the writer's power of observation and willingness to faithfully record these observations on a regular basis. Length of record does not necessarily equal quality; many shorter series may be of much greater reliability.

Nonetheless, many very long series of diaries do serve as anchors for long time series such as those used to produce the Central England temperature (CET) series (Manley, 1974). Multiple overlapping diaries from the same locality can be found in continuously occupied areas to cross-check each

observer for consistency and reliability in a general sense. The observers can be ranked for general reliability, and certain specific weather elements may be observed more keenly by one observer than by others. In general, even the diaries of poorer quality can contain information that is unique due to the particular interests and motivations that drive the writer to keep the record in the first place. A farmer, a shopkeeper, a fisherman, a lighthouse keeper, a plantation owner, a clergyman, and a surveyor will all have different perspectives and motivations for recording weather data. The sensitivity of their particular occupations may well drive the relative frequency of certain types of weather events being recorded in their diaries with respect to other weather events.

Government and Other Official Records

Many crops and foodstuffs grown by man are so important to their local economies that extensive documentation on their production exists in local-, regional-, and national-level government archives. Although no single location has a continuous record, it is possible to piece together similar type documents from the immediate area to produce a long-term climate series. Pfister et al. (1994) document an extensive database of European meteorological data gathered over a period of many years and discuss the methods involved in reconstructing temperature and precipitation indices. A good example of the type of data in official records is from viticultural records. The French wine-growing region of Burgundy contains extensive documentation from a number of vineyards that record the wind harvest dates as far back as the year 1370. Chuine et al. (2004) produced a record of Burgundy spring and summer temperatures estimated from the relationship between wine output and spring–summer temperature in the years 1960–1989. Such records are so far relatively rare as the extensive work of extracting the scattered documents and combining them into a continuous series is time consuming. Such results show how an interdisciplinary approach between historians and climatologists can extract valuable climate data from a

Figure 1 The logbook of HMS Lincoln, moored at Lynhaven Bay, Virginia, 28 Jul–6 Aug 1700 (detail). A typical example of the daily weather and significant activity on a Royal Navy ship provided in a logbook while the ship was at anchor in port. From the UK National Archives.

Table 1 Frequency of the most common wind force terms in the 420 British Royal Navy ships' logbooks, by decade, from 1691 to 1820, expressed as a percentage frequency of each decade's total number of observations

Decade	Percentage of wind force terms										
	Little wind	Small gale	Moderate gale	Fresh gale	Strong gale	Hard gale	Light airs	Light breeze	Moderate breeze	Fresh breeze	Strong breeze
1691–1700	9.4	9.4	20.1	33.5	3.5	24	0	0	0	0	0

Data are for ship encounters with tropical cyclones in the North Atlantic, so the values are not representative of climatological values in all weather. However, usage of specific wind force terms is accurately captured. Over time, some wind force terms go out of use while others came into use.

combination of modern data, historical documents, and a statistical model. While not all records will extend back more than 600 years, there are still many such records of shorter length that may be produced from historical records. Accounts from both private and local government sources of income loss from revenue sources such as tolls due to the freezing, flooding, and drying up of navigation channels provide examples of other records that are available for use.

Newspapers and Government Gazettes

A fruitful source for weather data from many areas of the world is the newspaper. Newspapers first began to appear in Europe in the seventeenth century, first in the form of officially sanctioned gazettes (which continued into the twentieth century in many parts of the world) and then into privately owned newspapers that proliferated in both Europe and North America and their colonies in the eighteenth century. Descriptions of natural wonders and disasters caused by the weather were common since most food production was local and trade restrictions between nations were often in force. News of weather-induced shortfalls in local food or crop production spread quickly among merchants, plantation owners, and government officials, who often formed the core of the newspaper subscriber base. Newspapers routinely provided the account of the impact of weather on food supplies and availability, shipping, and local damage reports. These include the inability to mill grain due to low river levels, the inability of ships to reach their

Figure 3 A personal weather diary for 1–11 Aug 1835 taken from the diary of Charles Heyward at his plantation in South Carolina, part of the Heyward family papers. Courtesy of Curator of Manuscripts, South Caroliniana Library, University of South Carolina, Columbia, South Carolina.

destination due to either too little or too much water, crop yields and the weather factors causing a shortfall or windfall; extremes of heat and cold causing excess deaths or raising the price for scarce fuel material; tornados, hail, and thunderstorms damaging crops, killing farm animals, and people; references to earlier instances of similar weather and other impressionistic descriptions of how unusual the weather appeared to the people at that time; weather events in foreign regions that would be of interest to merchants involved in trade with the affected region. In some instances, local weather diaries were published in newspapers providing another source of data for the historical climatologist (Figure 4).

Newspaper accounts provide weather from ships at sea encountering bad weather, since ships were the only source of transoceanic shipment of cargo and people until the twentieth century. Incoming ships described their encounters with gales, calms, lightning strikes, hurricanes, thick fogs, snowstorms, icebergs, heavy seas, and other phenomena which may be otherwise lost as most ships' logbooks are no longer extant.

In many instances, there are other official and private documents that also cover items recorded in newspapers. Initial accounts of ships lost at sea are often followed up by government and merchant records concerned with recording damages and losses for insurance and other claims made by owners,

Figure 4 Daily weather record for May 1786 for Nassau, Bahamas published in The Bahama Gazette of 27 May–3 Jun 1786. Air temperatures at 7 a.m., 2 p.m., and 9 p.m. are provided along with prevailing winds and weather conditions for each day. The original record is not known to be extant so the newspaper provides the only evidence of its existence.

passengers, crew, and other claimants. Newspaper accounts should not be considered to be the last word on weather impacts, but they do offer the widest variety of historical weather and weather impact data that can lead the historian and climatologists to other source documents.

Methods of Historical Climatology Research

Paleoclimate studies relying on historical documents incorporate these sources in different ways. The most common method is to extend a preexisting instrumental record as far back in time as the documents provide by comparing overlapping portions of different records to create a single climatologically homogeneous composite series. The CET series is a good

example of such a record (Manley, 1974; Parker et al., 1992). Production of such long time series involves the comparison of different weather record sources that overlap one another in time, which allows a direct comparison of their differences to be measured and adjusted via statistical techniques (often a regression model) so that nonclimatic biases (from different site exposures, times of observation, different instruments, and other methodological differences) are removed and a continuous time series, with estimated margins of error in the derived values, of one or more meteorological variables are produced. Parker and Horton (2005) provide an admirable example of determining both random and systematic errors in temperature data that should inform any approach to climate data reconstruction. Other studies use historical documents to serve as independent checks on another proxy source climate

Figure 5 Reconstructed spring–summer temperatures for Dijon, France from grape harvest records, 1370–2003 (Chuine et al., 2004). Figure derived from Pfister C (1993) Historical Weather Indices from Switzerland. IGBP PAGES/World Data Center-A Paleoclimatology Data Contribution Series #93-027. NOAA/NGDC Paleoclimatology Program, Boulder, CO, USA.

record (e.g., tree-ring reconstructions of precipitation and historical and archaeological records (Stahle et al., 1998)). The validity of this method assumes that the historical documentary record has been compiled in a consistent manner and uses reliable original sources. In other work, long records of weather event types, such as grape harvest dates in France (Chuine et al., 2004; Figure 5), El Niño events off the coast of South America (Quinn and Neal, 1983), and drought and flood chronologies in southern Africa (Nash and Endfield, 2002) are gathered to reconstruct a particular aspect of the Earth's climate system. Multivariate calibration methods employing both historical data sources and other proxy records with annual resolution are compared with climate models to assess the climate sensitivity of the models and to compare model-based spatial patterns of climate variability with the proxy-based record.

Discontinuous records can also provide information on past climate. Japanese instrumental temperature records are continuous only back to the 1870s, but colonial Dutch records now provide several decades worth of data back to 1819 which can still be compared with modern data (Können et al., 2003). Sometimes a modern data set is not needed to produce significant results. For example, short episodes of volcanic-induced global cooling were derived from a 21-year series of ships' logbooks from the early nineteenth century that is not continually linked to the modern record but used only a contemporary reference period to measure the short-term volcanic-induced temperature anomalies (Chenoweth, 2001).

Our understanding of history can be altered from historical climatology research. Climate descriptions of the American Great Plains once were thought to be artificial creations of the human mind but are now known from climate reconstructions to reflect actual climate anomalies (Lawson and Stockton, 1981). These early encounters with the weather colored the expectations of subsequent emigrants to the region and helped to shape its political growth and future economic path (Mock, 2000). Historical events of great importance are sometimes shaped in part by the role of weather as the Spanish Armada Storms of 1588 (Douglas et al., 1978). In turn, evidence of unusual climate extremes can sometimes be found by employing a synoptic approach to historical data (Chenoweth, 1996; Kingston, 1988). In this approach, multiple document types (e.g., journals, logbooks, letters, newspaper articles, legal documents) can be applied to map subdaily to monthly scale weather phenomena.

Suggestions for Future Research

Future research using documentary historical weather should focus on several fronts, and be adaptable to new discoveries from other fields of research as well as those in climatology. First, the construction of catalogs of known or likely sources of weather records needs to be compiled for all regions of the world. The National Oceanic and Atmospheric Administration (NOAA) historical climate data catalog is being produced for data from the United States, and the World Meteorological Organization (WMO) ARCHISS data survey project has located new sources in Central and South America. Only by knowing the amount and type of data available can scientists, in cooperation with other social scientists and historians, exploit the sources that have the best potential for filling in missing data from the historical record. Surveys of libraries and archives, including online database searches, are making it easier for such data to be located. Second, given knowledge of the availability of data sources, the records of areas that are known to be colocated in regions where important 'centers of action' are known to exist, such as the monsoon regions of India, the eastern tropical Pacific Ocean, high latitude sites, or areas where data can complement existing climate indices, such as the Caribbean region, where trade wind fluctuations are associated, in part, with fluctuations in the North Atlantic oscillation, should be chosen. Such studies can assist in determining the relative nonstationarity of the climate system and provide invaluable data on natural variability prior to anthropogenic effects on climate. Any record determined to be of good quality, regardless of its geographical location, should be closely studied. By extending the length of existing records, there is additional data available for calibration of proxy data sets. The creation of new data sets provides new data to be used as an independent data source to evaluate previous results, as well as being available for inclusion in future single or multiproxy climate reconstructions. Third, the original source documents should always be used when available. There are no shortcuts to the production of high-quality historical climate records. Fourth, different research communities must continue to reach out and share data and ideas. This process of knowledge diffusion will ensure that the value of the large amounts of historical data still awaiting use is recognized for its cultural, historical, and scientific value.

Paleoclimate Relevance to Global Warming

S H Schneider and M D Mastrandrea, Stanford University, Stanford, CA, USA

© 2013 Elsevier B.V. All rights reserved.

This article is reproduced from the previous edition, volume 3, pp. 2010–2020, © 2007, Elsevier B.V.

The Earth's climate is vastly different now from what it was at the beginning of the Quaternary period. It is different from what it was 20 000 years ago when ice sheets covered much of the Northern Hemisphere. Climate changes in the past were driven by natural causes, such as variations in the Earth's orbit or the carbon dioxide (CO₂) content of the atmosphere. Current and future climatic changes, however, have another source as well – human activities. Humans cannot directly rival the power of the natural forces driving the climate, such as the immense energy input from the Sun. They can, however, indirectly alter the natural flows of energy enough to create significant climatic changes.

Anthropogenic climate change is a problem of potentially great significance for the Earth's future. Many activities associated with human economic development have changed and are changing our physical environment in unprecedented ways. CO₂, methane (CH₄), and water vapor are the principal heat-trapping greenhouse gases. Carbon, the main element in the top two human-enhanced greenhouse gases (CO₂ and CH₄), is the underpinning of most fuels used in transportation and energy production. Carbon also makes up approximately half of the dry weight of most vegetation. Thus, the carbon that cycles through biological species, air, water, and soils is both an essential nutrient and a potential problem, depending on its location in the system. Human modification of the carbon cycle has far-reaching implications for human welfare and the health of the biosphere.

Although the changes that force anthropogenic climate change are unprecedented – and thus paleoclimatic conditions are not analogous to future anthropogenic changes – paleoclimate is a backdrop against which the understanding of the climate system can be calibrated, an understanding essential to have confidence in climate models, the tools used to project future changes. Many scientists conducting research to gain understanding of specific aspects of the climate system and the cycles or events that drive it benefit from studies of past climate changes in the paleoclimatic record, revealed through climate proxies.

This article focuses on how the paleoclimatic record can help understand anthropogenic climate change and how researchers have used that information to advance the knowledge of human interactions with the climate system.

Anthropogenic Climate Change

Scientific Consensus

It is scientifically well established that the Earth's surface air temperature has warmed significantly during the past 150 years, and an upward trend can be clearly discerned by plotting historical temperatures. [Figure 1](#) shows the observed global temperature record as a plot of the yearly deviations

from the 1961–90 average temperature. A glance at [Figure 1](#) shows that Earth's temperature is highly variable, with year-to-year changes often masking the overall rise of approximately 0.7 °C. Nevertheless, the long-term upward trend is obvious. Especially noticeable is the rapid rise at the end of the twentieth century. [Figure 1](#) shows that the 20 warmest years of the twentieth century include the entire decade of the 1990s and all but three years from the 1980s as well. The beginning of the twenty-first century has not changed this trend. 2001–2004 are among the five warmest years on record, exceeded only by 1998, the all-time record high through 2004. There is good reason to believe that the 1990s would have been even hotter had the eruption of Mt. Pinatubo in the Philippines not put enough dust into the atmosphere to cause global cooling of a few tenths of a degree for several years. Clearly, the recent past has seen substantial surface warming. This surface thermometer record has been matched by shrinking of the vast majority of mountain glaciers, warming in the oceans, shrinking of Arctic Sea ice, and responses of plants and animals (e.g., earlier bloom dates in the spring and earlier arrival dates of migrating birds).

Radiative Forcing

In addition, it is well established that human activities have caused increases in radiative forcing, with radiative forcing defined as a change in the balance between radiation coming into and going out of the Earth–atmosphere system. The annual average atmospheric concentration of carbon dioxide is currently approximately 378 ppm. In the past few centuries, atmospheric carbon dioxide has increased by more than 30%, as indicated in [Figure 2](#), and the predominant cause is human activity – the burning of fossil fuels and, to a considerable extent, land use changes such as deforestation. As shown in [Figure 2](#), concentrations of other greenhouse gases and other radiatively active atmospheric components, such as sulfate aerosols, are rising as well due to human activities. Although there is uncertainty regarding the current level of anthropogenic radiative forcing, it is well established that the greenhouse gas and aerosol concentrations indicated in [Figure 2](#) are affecting the energy balance of the climate system and contributing to the observed warming shown in [Figure 1](#). An in-depth treatment of the various contributors to anthropogenic radiative forcing is beyond the scope of this article. For more information, refer to the references at the end of the article.

'Fingerprints' in the Paleoclimatic Record

Could the warming shown in [Figure 1](#), especially of the past few decades, be a natural occurrence? Might Earth's climate undergo natural fluctuations that could result in the

Figure 1 Variation in Earth's average global temperature from 1860 to 1999. Data are taken from global networks of thermometers, corrected for a variety of effects, and combined to produce a global average for each year. Wide bars represent temperature deviations for each year, relative to the 1961–90 average temperature, and narrow bars show uncertainties in the yearly temperatures. The black curve is a best fit to the data. Adapted from Wolfson R and Schneider SH (2002) *Understanding climate science*. In: Schneider et al. (eds.) *Climate Change Policy*, p. 1. Washington, DC: Island Press.

temperature record of [Figure 1](#)? Increasingly, it has been found that the answer to that question is 'no.' One would be in a better position to determine whether the temperature rise of the past century is natural if the record could be extended further back in time. Unfortunately, direct temperature measurements of sufficient accuracy or geographic coverage simply do not exist before the mid-1800s, if then. However, by carefully considering other quantities that do depend on temperature, climatologists can reconstruct approximate temperature records that stretch back hundreds, thousands, and even millions of years.

The paleoclimatic record can tell more about how anthropogenic changes compare to naturally induced changes in the past, both in magnitude and in rate. It can provide more information about the behavior of processes in the climate system under conditions other than present conditions. It can also impart specific information about ecosystems of the past and how ecosystems may change in the future with anthropogenic climate change.

Methods used to attribute observed warming trends to anthropogenic climate change are often called 'fingerprint analysis.' Although each fingerprint may be a circumstantial piece of evidence for human-induced climate changes, taken together, many such lines of evidence have led the Intergovernmental Panel on Climate Change (IPCC, 2001) to conclude that there is a discernible human fingerprint on climate change. For example, the Earth's stratosphere has cooled while the surface has warmed – a fingerprint of changes due to increased atmospheric CO₂ rather than, for example, a fingerprint of an increase in the heat output of the Sun that should have warmed all altitudes in the atmosphere (Schneider, 2003).

Instrumental Record

[Figure 3](#) shows three different attempts, using the same climate model, to reproduce the historical temperature record of [Figure 1](#). In the model runs of [Figure 3\(a\)](#), only estimates

of solar variability and volcanic activity – purely natural radiative forcings – were included. The projected temperature variation, represented by a thick band indicating the degree of uncertainty in the model calculations, does not show an overall warming trend and clearly is a poor fit to the actual surface temperature record. The runs of [Figure 3\(b\)](#) include only anthropogenic forcings, such as emissions of greenhouse gases and aerosols. This clearly does a much better job of reproducing the observed temperatures, especially in the late twentieth century, but deviates significantly from the historical record around midcentury. Finally, [Figure 3\(c\)](#) shows the results from runs that include both natural and anthropogenic forcings. The fit is excellent, and the model runs of [Figure 3](#) taken together strongly suggest that the temperature rise of the past few decades is unlikely to be explained without invoking anthropogenic greenhouse gases as a significant causal factor. [Figure 3](#) provides substantial circumstantial evidence of a discernible human influence on climate and, with the other evidence mentioned, supports the IPCC conclusion that most of the warming observed during the past 50 years is attributable to human activities (IPCC, 2001).

Last Millennium

[Figure 4](#) shows the results of a study that attempts to push the Northern Hemisphere temperature record back a full 1000 years (Mann et al., 1999). In this work, climatologist Michael Mann and colleagues performed a complex statistical analysis involving 112 separate indicators related to temperature, including such diverse factors as tree rings, the extent of mountain glaciers, and changes in coral reefs. The resulting temperature record of [Figure 4](#) is a 'reconstruction' of what one might expect had thermometer-based measurements been available. Although there is considerable uncertainty in the millennial temperature reconstruction, as shown by the error band in [Figure 4](#), the overall trend is most consistent with a gradual temperature decrease during the first 900 years,

Figure 2 Records of the atmospheric concentrations of three well-mixed greenhouse gases (carbon dioxide, methane, and nitrous oxide) during the past 1000 years and records of sulfate aerosols since 1600. Adapted from IPCC (2001). In: Houghton JT, Ding Y, Griggs DJ, Noguer M, van der Linden PJ, Dai X, Maskell K, and Johnson CA (eds.) *The Scientific Basis – Contribution of Working Group I to the Third Assessment Report of the Intergovernmental Panel on Climate Change* Cambridge, UK: Cambridge University Press.

followed by a sharp upturn in the twentieth century. That upturn is a compressed representation of the thermometer-based temperature record shown in Figure 1. Among other things, Figure 4 suggests that the 1990s was the warmest decade not only of the twentieth century but also of the entire millennium. Taken in the context of Figure 4, the temperature rise of the last century clearly is an unusual occurrence.

Mann et al. (1999) correlated their temperature reconstruction with several factors known to influence climate, including solar activity, volcanism, and humankind's release of greenhouse gases. They found that solar variability and volcanism (natural influences) were the dominant influences in the first 900 years of the millennium but that much of the twentieth-

century variation could be attributed to human activity. Given the indirect, statistical nature of the study, this result can hardly be taken as conclusive evidence that humans are to blame for twentieth-century global warming. However, this result does provide independent corroboration of studies such as the one in Figure 3, which also indicate a human influence on climate. Similar results have also been shown in other studies, such as Jones et al. (2001) and Mann et al. (1998). This record has been pushed back two millennia (Mann and Jones, 2003), yielding similar results.

Ice Cores

Ice cores bored from the Greenland and Antarctic ice sheets provide estimates of both temperature and atmospheric CO₂ dating back hundreds of thousands of years (Jouzel et al., 1987; Petit et al., 2000). The ice cores have yielded a continuous record of the past 740 000 years (EPICA Community Members, 2004), and scientists expect that the record may be extended 1 million years into the past (White, 2004). Variations in ice density associated with seasonal snowfall patterns provide a highly time-resolved calibration of the age of given points in a given ice core, and analysis of air bubbles trapped in ancient ice gives an indication of CO₂ concentration. Temperature inference is accomplished by comparing a ratio of oxygen isotopes that is sensitive to temperature. Temperature differentially affects the concentration of the isotopes in evaporating water, and therefore their concentration in precipitation and in the ice. The result of such an ice core analysis, shown in Figure 5, gives dramatic evidence that temperature and CO₂ concentration are correlated over the long term.

It is not clear from the graph alone that the CO₂ variations in Figure 5 are the cause of the temperature changes. Sometimes, a CO₂ increase precedes a warming, but sometimes it does not. In fact, climatologists suspect a feedback process whereby a slight increase in temperature, probably caused by subtle changes in the Earth's orbit, results in an increase in atmospheric CO₂ through a variety of mechanisms, such as the release of CO₂ dissolved in the oceans (IPCC, 2001). The increased atmospheric CO₂, in turn, leads to greenhouse warming, amplifying the initial temperature increase. The result is a nearly simultaneous and substantial increase in both CO₂ and temperature. Eventually, orbital changes trigger a modest temperature decrease, and again feedback mechanisms amplify the decrease, driving down both CO₂ and temperature. Some paleoclimatologists also posit biotic feedback mechanisms, such as an initial cooling that causes a drying of the continents, producing more windblown dust (IPCC, 2001). This dust contains minerals needed by phytoplankton in the oceans. As dust settles on the ocean surface, it fertilizes these tiny oceanic organisms. The phytoplankton, in turn, increase their productivity by drawing down atmospheric CO₂, thus making the move toward an Ice Age even more rapid and deep. However, despite such complexities, there is still much regularity in the record. The pattern of varying temperature and CO₂ concentration shown in Figure 5 is believed to repeat on a timescale of roughly every 100 000 years over most of the past 1 million years, at least in part as a result of periodic changes in the Earth's orbit and the inclination of its polar axis.

Figure 3 Attempts to model Earth's temperature from the 1860s using different model assumptions. In all three graphs, the solid curve is the observed surface temperature record of Figure 1. Gray bands represent model projections. In each graph, the bands encompass the results of four separate model runs. In (a), only natural forcings – volcanic activity and solar variability – are included. Clearly, this simulation lacks the upward trend in the observed temperature record, suggesting that the temperature rise of the past century and a half is unlikely to have a purely natural explanation. Simulation (b), including only anthropogenic forcings, does much better, especially with the rapid temperature increase of the late twentieth century. Simulation (c), combining both natural and anthropogenic forcings, shows the best agreement with observations. Adapted from Wolfson R and Schneider SH (2002) Understanding climate science. In: Schneider et al. (eds.) *Climate Change Policy*, p. 1. Washington, DC: Island Press. Data from IPCC (2001). Figure 4 Reconstruction of the 1000-year temperature record for the Northern Hemisphere. The black curve is a best fit to the millennial temperature record; gray is the 95% confidence interval, meaning that there is a 95% chance that the actual temperature falls within this band. Data from the mid-19th century on are from the thermometer-based temperature record of Figure 1. Adapted from Wolfson R and Schneider SH (2002) Understanding climate science. In: Schneider et al. (eds.) *Climate Change Policy*, p. 1. Washington, DC: Island Press.

Note that Figure 5 shows brief periods of warmth punctuated by much longer, cooler Ice Ages, which are characterized by dramatically different climatic conditions, with ice sheets 2 km thick covering what is now Canada, the northeastern United States, and northwestern Europe and engulfing high mountain plateaus throughout the world. Today, humans enjoy the warmth of an interglacial period, but not long ago, geologically speaking, conditions were very different. Figure 5 shows that the difference in temperature between an interglacial and an Ice Age is on the order of 6 °C. Climate models driven by standard assumptions about population, land use, and energy consumption project a warming over the next century of 1.5–6 °C. The difference between the higher and lower ends of this range has substantial implications for sea-level rise, extreme weather, redistribution of species ranges, and other impacts. Policymakers and the general public often ask how a few degrees can matter all that much. Figure 5 provides one striking answer: Downward changes on the same order as the largest projected warming are enough to make the difference between the current climate and an Ice Age.

Note in Figure 5 that the maximum CO₂ concentration in the ice core record of the past 160 000 years is less than

Figure 5 Atmospheric carbon dioxide (top curve) and temperature variation (bottom curve) during the past 160,000 years, from ice cores taken at Vostok, Antarctica. The record shows long stretches of low temperature (Ice Ages) separated by brief, warm interglacial periods. The correlation between CO₂ and temperature is quite obvious. Note also the small change, averaging perhaps 6 °C, between the present warm climate and the recent Ice Age. Data do not extend to the present, but stop well before the industrial era. Adapted from Wolfson R and Schneider SH (2002) *Understanding climate science*. In: Schneider et al. (eds.) *Climate Change Policy*, p. 1. Washington, DC: Island Press. CO₂ data are from Petit JR et al. (2000) *Historical isotopic temperature record from the Vostok ice core*. In: *Trends: A Compendium of Data on Global Change*. Oak Ridge, TN: Oak Ridge National Laboratory, Carbon Dioxide Information Analysis Center. Temperature data are from Jouzel J et al. (1987) *Vostok ice core: A continuous isotope temperature record over the last climatic cycle (160,000 years)*. *Nature* 329: 403–408, as reproduced in the Carbon Dioxide Information Analysis Center.

Figure 6 The CO₂ record of Figure 5, with data up to 2004 included. The CO₂ rise of Figure 2 is shown here as a dramatic jump to levels not seen on Earth for hundreds of thousands (and probably millions) of years. Adapted from Wolfson R and Schneider SH (2002) *Understanding climate science*. In: Schneider et al. (eds.) *Climate Change Policy*, p. 1. Washington, DC: Island Press.

300 ppm. This does not include the very recent past, but only the preindustrial period. The present-day concentration of 378 ppm is far above anything the Earth has seen, probably for millions of years. Figure 6 shows the effect of adding the

recent rise in CO₂ to the ice core data. Clearly, the anthropogenic increase in CO₂ concentration is unprecedented in both its size and its rapidity. The human race has made truly dramatic changes in the Earth's atmosphere during the past century or so, and significant climate change can be expected as a result of these changes almost certainly.

Finally, a very unique 'fingerprint' study was conducted by Ruddiman (2003). Ruddiman believes that atmospheric concentrations of CO₂ and CH₄ were first altered by humans thousands of years ago, resulting from the discovery of agriculture and subsequent technological innovations in farming. Ruddiman analyzed the Pleistocene CO₂ record by examining the Vostok ice core and came to the conclusion that the interglacial life cycle of CO₂ in the present interglacial has varied from the other three interglacials occurring in the past 400,000 years. In typical interglacials, CO₂ peaks early and then stabilizes or decreases, but in the Holocene interglacial, CO₂ levels fell early on and then began to recover. Ruddiman believes the main difference between this abnormal interglacial and the others is the presence of land clearing and agriculture. He points to two ways in which land clearing typically increases CO₂ concentrations: burning and decomposition of downed vegetation and increased weathering of soil carbon in a system that has been disturbed (i.e., tilled). These forces, Ruddiman believes, warmed the Earth by a global mean of approximately 0.8 °C in recent millennia (2 °C at higher latitudes) and have contributed to an uncharacteristically stable 10,000 years. Although there are many unresolved uncertainties in this work, this is an area ripe for additional research.

Climate Processes

Beyond changes in mean temperature, the paleoclimatic record can also tell us much about past climate variability, including interannual variability driven by such processes as El Niño–Southern Oscillation (ENSO), North Atlantic Oscillation, and changes in the meridional overturning circulation in the North Atlantic, also known as the thermohaline circulation. Again, other articles in this encyclopedia focus specifically on these issues, and therefore a detailed treatment of these issues has not been presented here. However, study of the past behavior of the climate system may allow scientists to project more confidently the changes in climate processes that could occur under anthropogenic climate change.

For example, a number of studies have used paleoclimatic proxies to produce reconstructions of ENSO variability prior to the instrumental record (Mann et al., 2000; Stahle et al., 1998), focusing on proxies for sea surface temperature in the equatorial Pacific, where key processes determining the evolution of the ENSO cycle occur. Jones et al. (2000) compared these reconstructions back to the early 1700s and compare them to observational data back to the late 1800s. They found that both records exhibit similar interannual and interdecadal variability, and that the recent period marked by frequent warm phase (El Niño) events is unique in one record (Stahle et al., 1998) and is unique since 1800 in the other (Mann et al., 2000), although uncertainty in the reconstructions prevents high confidence in such conclusions. However, such findings lend plausibility to projections of future changes in the ENSO cycle

under anthropogenic climate change, such as Timmermann et al. (1999) suggested. Timmermann et al. used a complex global climate model to simulate the ENSO cycle under future climate change and found that in their model, more frequent warm-phase (El Niño) conditions and more intense cold-phase (La Niña) events occurred.

Climate Modeling and the Paleoclimatic Record

Several ways in which the paleoclimatic record can directly provide information about the climate system and potential responses of the system to anthropogenic climate change have been discussed. Simulation of the climate system is a complex undertaking. The ideal model would include all processes known to have climatological significance and would involve fine-enough spatial and temporal scales to resolve salient phenomena occurring over limited geographical regions and relatively short time spans. Today's most comprehensive models strive to reach this ideal but still entail many compromises and approximations. As mentioned previously, the paleoclimatic record also provides the backdrop against which climate modelers can calibrate and test their models, lending their future projections more credibility. This section provides several examples of ways in which the paleoclimatic record is used in climate modeling, covering model validation, model calibration, and modeling of ecosystem dynamics.

Model Validation

How can modelers be more confident in their model results? How do they know that they have taken into account enough climatologically significant processes, and that they have satisfactorily parameterized processes for which the spatial scale are below that of their models' grid cells? The answer lies in a variety of model validation techniques, most of which involve evaluating a model's ability to reproduce known climatic conditions in response to known forcings.

One way to gain confidence in a model's ability to predict future climate is to evaluate its accuracy in modeling past climates. Can the model, for example, reproduce the temperature variations from 1860 to the present charted in Figure 1? Figure 3 is an 'experiment' with one climate model to do just that. The excellent fit between observed and modeled temperatures, in Figure 3(c), suggests greater confidence in this model's projections of future climate.

In one of the seminal comparisons of paleoclimatic data and climate models, members of the Cooperative Holocene Mapping Project (COHMAP) compiled an extensive library of paleoclimatic data to create a reconstruction of the climate of the past 18 000 years and compared the data to modeled representations of the paleoclimate using the National Center for Atmospheric Research's Community Climate Model (CCM). Their well-known *Science* article (COHMAP Members, 1988) summarizes many of their comparisons. Basing their modeling of the changes in the seasonal and latitudinal distribution of solar radiation predicted by the Milankovitch theory, the COHMAP project was able to reproduce many of the paleoclimatic conditions consistent with their paleoclimatic data set of pollen, plankton, and lake level records. For example, Figure 7

Figure 7 Comparison of observed lake levels in the northern tropics during the past 18 000 years with a model simulation of the moisture budget (precipitation – evaporation). Adapted from COHMAP Members (1988) Climatic changes of the last 18,000 years: Observations and model simulations. *Science* 241: 1043–1052.

shows a comparison of observed lake levels in the northern tropics during the past 18 000 years with a simulation of the moisture budget (precipitation minus evaporation) by CCM. Although the agreement is not perfect, the model output correctly displays a maximum for the moisture budget of 6–9 ka, when lake levels were at their maximum. This represents one of the first regional-scale validations of a complex climate model.

Anthropogenic radiative forcings projected to 2100 are different than any known in the past, and there is no direct way of empirically testing the model's performance – except to wait until the Earth's climate system performs the 'experiment.' However, testing the models against such known paleoclimatic and paleoecological variations gives considerable confidence that these models are treating the essential climate-determining processes with reasonable fidelity, and it can therefore be expected of them to produce moderately realistic projections of future climate, at least at the large scale, given credible emissions scenarios.

Variations in the projections of different models are still expected, and because future greenhouse gas emissions depend on human behavior, future projections will differ depending on what assumptions modelers make about the human policy responses to the prospect of global warming. The uncertainties in projections of human behavior cause about as much spread in estimates of future warming as do uncertainties in the understanding of the sensitivity of the climate system to specified radiative forcings.

Model Calibration

Much of the uncertainty in current understanding of the climate system is captured by the so-called climate sensitivity, defined as the equilibrium global mean surface temperature increase from a doubling of atmospheric CO₂. Using general circulation models, the IPCC has long estimated the climate sensitivity to be between 1.5 and 4.5 °C (IPCC, 2001), although other studies have produced distributions wider than the IPCC range, with significant probability of climate sensitivity above 4.5 °C (Andronova and Schlesinger, 2001; Forest et al., 2001; Stainforth et al., 2005). A detailed

description of the factors that contribute to uncertainty in climate sensitivity is beyond the scope of this article. However, the paleoclimatic record is a key source of information for determining the plausible range for this important parameter.

Given the uncertainties inherent in the feedback processes that must be incorporated into climate models, is there any way to estimate climate sensitivity empirically? One way is to use historical paleoclimatic situations in which both forcing and temperatures were different than those of the modern era. Hoffert and Covey (1992) attempted this estimation and arrived at a climate sensitivity in the range of 2–3 °C for a doubling of CO₂. Of course, precise forcings and temperatures are not available for the distant past, so a considerable degree of uncertainty exists in such empirical attempts. Nevertheless, they do add confidence that current ranges of climate sensitivity are not wildly unrealistic, and they suggest that the probability of climate sensitivities much above or below the long-standing 1.5–4.5 °C estimated range of warming for a doubling of CO₂ is not high.

More precise information on both temperature trends and radiative forcings exists for the past 50 years. If one were to estimate climate sensitivity by tracking how much warming occurred during the past 50 years and scaling this warming by the amount of radiative forcing (i.e., how many watts of radiation energy is added per square meter of earth) caused by greenhouse gas increases, a ratio of temperature rise to forcing (i.e., climate sensitivity) could be estimated. Thus, to empirically estimate the climate sensitivity, all the forcings need to be estimated and aggregated to find the net overall forcing number. Unfortunately, there will continue to be a very large range of uncertainty associated with estimates of the all-important climate sensitivity parameter. In fact, uncertainty in radiative forcings is at least a factor of three.

Andronova and Schlesinger (2000), for example, attempted to create a broad probability distribution for climate sensitivity by scaling the observed temperature trends against a range of possible forcings. Because of the uncertainties in forcing, they obtained a very broad distribution. Approximately 50% of the estimates for climate sensitivity lie outside of the IPCC's 1.5–4.5 °C range. Other groups have attempted semiempirical estimation of climate sensitivity, obtaining similar results to those of Andronova and Schlesinger (Forest et al., 2001; Murphy et al., 2004).

Hegerl et al. (2003) completed a similar analysis using a reconstruction of temperature and radiative forcing during the past millennium, obtaining similar results. During this longer time period, aerosol forcing, which is the dominant source of uncertainty in recent times, is relatively unimportant, and the responses to relevant forcings (greenhouse gases, solar variability, volcanism, and land use change) can be separated more effectively than for the shorter instrumental period.

Ecosystem Dynamics

Since anthropogenic climate change is proceeding, on a sustained globally averaged basis, at an order of magnitude faster than Pleistocene/Holocene climatic changes, dramatic and differential responses of plant, insect, mammal, and bird species can be anticipated. Thus, a very large restructuring and reorientation of biological communities seems likely. Future

climates may not only be quite different from more recent previous climates but also be different from those inferred from paleoclimatic data and from those to which some existing species are evolutionarily adapted. Therefore, these data cannot provide direct analogs for future assemblages under anthropogenic climate change, but they can provide a means to calibrate and verify models to predict future ecosystem dynamics (Crowley, 1993; Schneider, 1993).

For example, Figure 8 displays paleovegetation maps during the past 18 000 years, reconstructed using the method of modern analogs and more than 13 000 samples of fossils and modern pollen. During the last Ice Age, most of Canada was under ice; pollen cores indicate that as the ice receded, boreal trees moved northward chasing the ice cap. One interpretation of this information was that biological communities moved intact with a changing climate. If this were true, the principal ecological concern regarding the prospect of future climate change would be that human land-use patterns might block what had previously been the free-ranging movement of natural communities in response to climate change. However, analyses by COHMAP, mentioned previously, incorporating multiple pollen types found that although nearly all species moved north, as expected, during the transition from the last Ice Age to the present interglacial, the distribution of pollen types provided no analogs to today's vegetation communities during a significant portion of the transition period (Overpeck et al., 1992). That is, whereas all species moved, they did so individually, not as groups of different species. The relevance of this is that in the future ecotypes will not necessarily move as a unit as climate changes (assuming there is time and space for such a migration). Additionally, past vegetation response to climatic change at an average rate of 1 °C per millennium indicates that credible predictions of vegetation changes from comparable or more rapid changes projected from human activities cannot neglect the time-evolving (transient) dynamics of the ecological system.

Conclusions

A brief description of the relevance of paleoclimatic research to global climate change has been given. Paleoclimatic research updates the human understanding of past climatic fluctuations, of the impacts of past climatic changes on physical processes and natural ecosystems, and of human capacity to model the climate system. Even if humans get the greenhouse gas emissions under control quickly, global temperature will continue to rise, and the effects of global climate change, particularly sea-level rise, will almost certainly continue to increase well beyond the end of the twenty-first century. The paleoclimatic record provides a critical source of information for understanding the climate of today and modeling the climate of the future.

Introduction

The term paleohydrology was first used in the fluvial literature by Leopold and Miller (1954) in their Geological Survey Water-Supply Paper on the postglacial chronology of alluvial valleys in Wyoming (USA). Leopold and Miller recognized that the interactions of climate, vegetation, stream regime and runoff would have been different under varying past climates and outlined a research agenda that is still relevant today. For example, in relation to the climate versus human impact debate, they stated that an "... understanding of our soil erosion problems and of the efficacy of control measures requires that we sharpen our tools for distinguishing those features of the modern landscape molded by natural forces alone and those related to activities of man. Geomorphology can provide techniques that will help us" (Leopold and Miller, 1954, p. 75). It was Stanley Schumm who developed paleohydrological concepts further, outlining his ideas in the *The Fluvial System* (Schumm, 1977). Therein, he defined paleohydrology as the "science of the waters of the Earth, their composition, distribution, movement on ancient landscapes from the occurrence of the first rainfall to the beginning of continuous hydrological records" (Schumm, 1977, p. 42). This somewhat cumbersome definition contradicts the neat concepts he articulated; Schumm recognized that rivers would respond in predictable ways, at least qualitatively, in response to changes in discharge regime and sediment loads. For the purposes of this article, fluvial paleohydrology can be defined as the study of fluvial processes and their hydrological implications before the onset of instrumental records (modified from Brown, 1997) and covers, therefore, the response to global change of: runoff and discharge regime; sediment transport and storage; and extreme floods.

Throughout the majority of the 50-plus-year history of fluvial paleohydrology, studies were primarily descriptive and qualitative in nature; however, recent methodological advances (Brown et al., 2009), for example, in (a) airborne and terrestrial light detection and ranging (LiDAR); (b) sub-surface remote sensing; (c) geographic information systems (GIS); (d) landscape, hydrological and flood hydraulic models; and (e) geochronology (e.g., accelerator mass spectroscopy (AMS) C-14 and optically stimulated luminescence (OSL) dating techniques), have enabled a quantification revolution in fluvial paleohydrology. This article will review recent developments in our understanding of Holocene fluvial systems through these methodological advances, with a particular focus on: (a) quantification of basin scale sediment transport and storage; (b) the quantification of paleoflood discharges; and (c) key debates regarding the drivers of fluvial response over different spatial and temporal scales, in particular, the relative roles of allogenic drivers (e.g., climate and land use land cover (LULC)) and autogenic drivers. Autogenic processes are particularly important to quantify and understand as they

cloud the links between fluvial system response and the controls of LULC and climate (e.g., Van De Wiel and Coulthard, 2010), identified as key issues in sustainable river management aimed at mitigating negative impacts of future global change. Indeed it is pertinent to note here the role of fluvial paleohydrology in contemporary river management as it is important for river managers to understand the long-term history and geomorphological evolution of fluvial systems (Sear and Arnell, 2006). This is not only due to changing fluvial processes over decadal and centennial timescales but also due to the long history of river management in many regions of the world (Hudson et al., 2008).

Long-Term Sediment Transport and Storage

Fluvial paleohydrological research over the last two decades has demonstrated that natural early Holocene floodplains, certainly in lowland low-energy river systems, were likely to be stable wetland environments (Walter and Merritts, 2008), with systems such as the Narew River in Poland, one of the few remaining anastomosing fluvial wetland environments to have survived channel management and floodplain drainage (Gradzinski et al., 2003), serving as a modern analog for many early Holocene rivers. Subsequent human impact over varying spatial and temporal scales has led to increased sediment loads and floodplain sedimentation rates resulting in floodplain alluviation, especially over recent millennia in a European context (Notebaert and Verstraeten, 2010). It is likely that these changes have fundamentally altered fluvial processes and river hydraulics. This was shown by Knox (2006) in the Upper Mississippi basin, where the relatively recent post-colonial human impacts of mining and agriculture have led to alluviation, while channel bed elevations have remained stable. This resulted in an increase in river channel capacity from 3.6 m² in AD 1832 to 24.8 m² in 1990, thereby increasing bankfull flood discharge and other flow hydraulics, such as bed shear stress and stream power, thus potentially increasing the geomorphic activity of the river. As de Moor and Verstraeten (2008) demonstrate, river systems shifted from a natural sediment supply (detachment)-limited system to an anthropogenic capacity (transport)-limited system with a high proportion of sediment stored as colluvium or in alluvial floodplains. In this section, sediment budget research aimed at quantifying long-term sediment transport pathways and storage will be discussed, as this has implications for the sensitivity of river systems to global change, and in particular climatic variability. For a detailed overview of methodologies, readers are directed to Brown et al. (2009).

It is only recently that there has been sufficient field data, allied to newly available data handling techniques (Brown et al., 2009), to enable the quantification of sediment storage at large spatial scales, such as the Rhine basin (Hoffmann et al.,

2009). Earlier studies tended to be qualitative, or focused on small spatial and/or temporal scales. Some of the most detailed quantitative sediment budgets available have been reconstructed for river basins of the European loess belt (de Moor and Verstraeten, 2008; Notebaert et al. 2009; Verstraeten et al., 2009). In the 55-km² Nethen basin, a tributary of the Dijle basin (Figure 1), Verstraeten et al. (2009) demonstrated that 38% of sediment eroded during the Holocene was stored in colluvium and dry valleys, with 23% as alluvium. In the Geul River catchment (380 km²), de Moor and Verstraeten (2008) applied a two-dimensional erosion and hillslope delivery model (WATEM/SEDEM), combined with geomorphic field data, to demonstrate that over the last millennium >80% of eroded sediment was stored as colluvium, suggesting the basin has been a capacity-limited system over this time span. Prior to this period, less sediment was generated within the basin and a high percentage was transported to the main river valleys or exported out of the system, thus the natural fluvial system was supply limited (de Moor and Verstraeten, 2008). In the Dijle catchment (758 km²), the sediment budget illustrated in Figure 1(b) shows that the total estimated erosion for the Holocene was 817 ± 66 Mt, of which 327 ± 34 Mt was deposited as colluvium and 352 ± 11 Mt on alluvial floodplains

(Notebaert et al., 2009). The sensitivity of sediment dynamics in the catchment was tested by Notebaert et al. (2011) using a modeling approach, the WATEM/SEDEM sediment model complemented through runoff modeling using a spatially distributed model (STREAM). The key findings demonstrate that of the observed increase in soil erosion from the early Holocene to the present (Notebaert et al., 2009), 9% of the increase is due to climatic variations while 6000% is due to land use change. These dramatic shifts account for the changing floodplain characteristics documented from floodplain boring surveys (Figure 1(a)), with a shift from peat-dominated stable wetland systems to alluviated, fine-grained floodplains, as also noted in the United States (Walter and Merritts, 2008). Regarding the modeled runoff, the mean discharge shows a possible slight increase from the early to late Holocene but there is greater change in peak flows (Figure 1(c)). For example, the modeled mean discharge for the Dijle catchment pristine scenario (4950–4851 BC) is 6.8 ± 1.3 m³ s⁻¹, compared to 7.2 ± 1.9 m³ s⁻¹ for the modern period (AD 1900–1999), while maximal discharges increase from 27.7 to 119.9 m³ s⁻¹ over this same period (Notebaert et al., 2011). The influence on extreme events can also be seen in the recurrence interval curves (Figure 1(d)) where the lowest discharges for the

Figure 1 Holocene sediment budget and paleohydrology of the Dijle River, Belgium. (a) A typical valley cross-section showing the peaty nature of the natural floodplain environment and anthropogenic alluviation, which increases in rate over the last millennium (Notebaert et al. 2009). (b) Holocene sediment budget for the Dijle River (Notebaert et al., 2009). (c) Modeled mean daily discharge for various Holocene LULC scenarios (Notebaert et al., 2011). (d) Recurrence interval curves for the same Holocene LULC scenarios as in (c) (Notebaert et al., 2011).

100- and 1000-year recurrence intervals are modeled for the older scenarios (4950–4851 BC and 3850–3751 BC). The increase in sedimentation due to human impact noted in small to medium basins of the loess belt is also evident at larger spatial scales in Europe, for example, in the Rhine basin, though the larger the spatial scale the more problematic it is to link cause and effect (Hoffmann et al., 2009). While a combination of sediment budgets and hydrological modeling attest to the importance of human impact in controlling sediment dynamics and fluvial regime in Western Europe (Notebaert et al., 2011), it is problematic in alluvial floodplain settings to test the variability of extreme hydrological events. Sedimentary flood records located in bedrock gorge settings, where flood magnitude can be reconstructed, will be considered in the next section.

Flood Response to Holocene Climatic Variability

Paleoflood hydrology, a subdiscipline of paleohydrology, is the reconstruction of the magnitude and frequency of floods, recorded in the instrumental flood record, using geomorphological evidence (based on the definition of Baker et al., 2002). Paleoflood hydrological techniques have primarily been developed through two research themes: (a) the quantification of extreme Holocene floods; and (b) the reconstruction of late Pleistocene megafloods (e.g., Carling et al., 2010). Paleoflood research combines geomorphic mapping of flood-related landforms and sediments (e.g., flood benches); the sedimentology and stratigraphy of flood deposits (Benito et al., 2003), including geochronological control; and hydraulic flood modeling (Webb and Jarrett, 2002), as used in conventional hydrology, to quantify paleodischarge. This section will focus on Holocene paleofloods and flood–climate relationships, though the role of human impact on flooding has also been documented (e.g., Benito et al., 2010).

Narrow bedrock gorges are the main geomorphic setting for paleoflood studies (Benito et al., 2003). The reasons for this are twofold: firstly, the channel geometry and valley cross-section is relatively stable so that channel changes are restricted and/or readily quantifiable; and secondly floodwater stage is sensitive to flood magnitude. This latter point can be seen in Figure 2(a), which shows a valley cross-section of the Llobregat River (NE Spain) with three paleoflood sites located at different elevations above the channel and therefore requiring different discharge thresholds to be reached before deposition can occur (Thorndycraft et al., 2005). The most utilized geomorphic flood evidence in paleoflood studies, as shown in Figure 2(a) and 2(b), are slackwater flood deposits. These are fine-grained sediments (silts and sands) deposited in marginal zones of bedrock gorges where flow separation creates eddies and zones of slackwater flow, promoting deposition of flood sediments and their preservation during subsequent events (Benito et al., 2003). Slackwater flood deposits are usually found associated with two distinct sediment–landform assemblages: (a) the infill of valley side alcoves; and (b) flood benches. Alcoves and small caves located along bedrock gorges may become inundated during floods and fine-grained slackwater flood sediments are deposited (Figure 2(a) and 2(b)). These sites usually afford excellent preservation, as the

sediments are protected from slope processes in between successive flood events and may be sealed by cave sediments, which help identify between flood events in the stratigraphic record. Flood benches are terrace-like morphological units which may be formed in areas of canyon expansion or on the inside of gorge meander bends. In appearance they are very similar to fluvial terraces, with a low relief upper surface and a clear scarp slope toward the river; however, the processes of their formation are distinctive. While terraces are abandoned floodplain surfaces, formed after river incision, flood benches result from the aggradation of slackwater flood sediments from successive flood events (Benito et al., 2003), the scarp slope at the edge of the bench formed by flood erosion approximately demarcating the transition from the main flood flow path from the zones of flow separation and slackwater.

For a detailed overview of the sedimentology of slackwater flood deposits, readers are directed to Benito et al. (2003). The key element of the stratigraphy of slackwater sequences, whether preserved in alcoves or flood benches, is the identification of individual flood events. The most common criteria for distinguishing flood events within a stratigraphic sequence are: (a) a distinct clay layer formed during the waning stage of a flood; (b) a layer of nonflood sediments that marks a clear boundary between two successive flood units, for example, a buried soil, or precipitated carbonates in caves; and (c) bioturbation indicative of an exposed sedimentary surface. The chronology of the paleoflood events are determined by standard geochronological techniques, usually AMS radiocarbon dating of organics transported during the flood, or the OSL dating of quartz sands within the deposits.

Webb and Jarrett (2002) outline a number of methods for the quantification of paleodischarge, though the usual approach is through step-backwater hydraulic flood modeling, for example, using the one-dimensional HEC-RAS (Hydrologic Engineering Center's River Analysis System) model developed by the US Army Corps of Engineers for testing the design of structures built on floodplains, for example. In paleoflood hydrology, an iterative approach is used whereby a range of flood discharges are routed through the surveyed study reach with the resulting modeled floodwater elevations matched to the mapped paleostage indicators identified along the reach. While consideration needs to be made to assess the potential model errors, for example, the determination of roughness coefficients, a quantified discharge estimate can be assigned for each geomorphic flood indicator along a reach. For most paleostage indicators such as slackwater flood sediments, this modeled discharge is a minimum discharge, the true floodwater stage was an unknown elevation above the deposited sediments; however, upper bound (nonexceedance) evidence may also be used to provide an upper limit of paleodischarge, for example, a terrace surface with no geomorphic evidence for inundation over a determined time interval (Levish, 2002).

Combining the methodological approaches described above provides data that can be interrogated to ascertain a paleoflood magnitude and frequency record. One example of this is the paleoflood record of the Llobregat River in NE Spain (Thorndycraft et al., 2005, 2006), presented in Figure 2. Figure 2(a) illustrates the paleoflood stratigraphy of three alcove sites located at different elevations above the channel bed, with the associated geochronological and paleodischarge

Figure 2 The paleoflood hydrology of the Llobregat River (NE Spain). Paleoflood stratigraphy, chronology and threshold discharges for (a) Monistrol (3370 km²) and (b) Pont de Vilomara (1845 km²). Reproduced from Thorndycraft VR, Benito G, Rico M, Sánchez-Moya Y, Sopena A, and Casas A (2005) A long-term flood discharge record derived from slackwater flood deposits of the Llobregat River, NE Spain. *Journal of Hydrology* 313: 16–31. (c) Extreme floods of the Llobregat River at Pont de Vilomara according to the gauge station record and paleoflood information. The paleoflood events are plotted according to the estimated minimum peak discharge and the midpoint of the radiocarbon error range, with the exception of the event dated to cal AD 1515–1640 which has been assigned to the 1617 event according to documentary evidence. The arrows indicate two undated events.

information annotated. The figure therefore shows flood magnitude frequency relationships for the Llobregat River, with low-magnitude high-frequency events preserved in the lower Alcove E; the largest floods of the instrumental record preserved at Alcove D; and an extreme event identified at Alcove C, the AMS dating of which provided an age of 1580–1740 cal. AD. Eight floods of similar magnitude at the upstream Pont de Vilomara site are illustrated for Alcove A (Figure 2(b)). The only dateable material for this sequence was found for the middle two flood units, but nevertheless this provides sufficient information to illustrate that at least five extreme magnitude events have occurred in the last 3000 years (Figure 2(c)). In addition to the two events that appear to date to the cold phase of regional climate centered on 2850 cal. BP, evident in the Bond curve, it has been assumed for Figure 2(c) that the most recent flood from this sequence is the same event at Alcove C at Monistrol (Figure 2(a)). This flood has been assigned, after cross-checking with the documentary flood record, to the known flood of AD 1617, believed to be the largest event of the last millennium. The combination of paleoflood with archival environmental history is of particular importance, as the 1617 flood can be seen to be one extreme event within a period of high magnitude and frequency flooding that occurred during particularly cold and dry decades of the Little Ice Age (LIA). From anecdotal reports on the timing of rainfall intensities and wind directions, coupled with a nested meteorological approach where events with increasingly less data and information were compared to modern analogs, synoptic conditions associated with the 1617 flood could be hypothesized

(Thorndycraft et al., 2006). The key factors that led to the flood were heavy rainfall centered over the upper basin (4–5 November 1617) followed by convective storms arriving in the littoral mountain range (lower basin) on the 6th November, coinciding with the flood peak arriving from the upstream. It appears that the event was associated with high pressure blocking over Central Europe and low pressure over the Iberian Peninsula drawing air up from North Africa and across the Mediterranean. Such synoptic conditions would have been more prevalent during cold phases of the LIA than at present, hence an increased probability of floods of such magnitude occurring in the LIA. This case study illustrates the importance of atmospheric circulation rather than moisture content of the atmosphere, as also demonstrated in the Upper Mississippi (Knox, 2000), for the generation of extreme floods at the basin scale.

Paleoflood hydrology, therefore, demonstrates that the magnitude and frequency of extreme floods can vary in response to climatic variability, and that in many river basins, gauge station flow records are of insufficient length to have recorded the largest flood flows. The next section considers whether these variations in flood magnitude and frequency can be seen to drive fluvial system response or whether it is LULC and/or autogenic processes that are the dominant control.

Drivers of Change

Much of the literature on fluvial paleohydrology attempts to define the roles of key allogenic drivers on fluvial system

response, in particular climatic variability and LULC changes, which links to the goal of hydrologists and river managers to predict future forcing of climate and LULC on flood hydrology. As we have seen, the human impact on alluviation in the European loess belt is compelling (Notebaert and Verstraeten, 2010), as is the evidence for extreme flood response to late Holocene climatic variability (Thorndycraft et al., 2005). However, the role of autogenic processes on the preserved stratigraphic record also need to be considered. While autogenic controls have long been recognized in the sedimentary record, recent methodological advances (Brown et al., 2009) now allow their improved quantification in Holocene alluvial records (e.g., Daniels, 2008; Erkens et al., 2009). Daniels (2008) suggested that autogenic bed elevation changes that are time-transgressive and propagate at predictable rates through a river basin, can be deciphered from allogenic forcing recorded in alluvial stratigraphic units correlated to a specific time interval and occurring over a larger spatial area. In the Upper Rhine Graben, Erkens et al. (2009) identified autogenic control of Rhine terrace formation during the Mid-Holocene. Due to the low valley slope in the graben reach of the Rhine, terrace incision is believed to have been initiated in response to meander cut-offs, causing a localized increase in gradient and therefore incision in response to higher stream power, rather than by any change in hydrology or sediment load.

It is interesting to note the contrast of opinions the fluvial paleohydrological community has reached with regards fluvial drivers. While Macklin et al. (2010, p. 1573) state that the “application of meta-analysis [of radiocarbon databases] ... is allowing for the first time the ‘signal’ of climate change and agricultural activity in the fluvial record to be quantified and distinguished from the ‘noise’ of autogenic river processes ...,” fluvial landscape evolution models have demonstrated in relation to long-term bedload transport that “identical system inputs ... can lead to drastically different outputs from each event ...” which means that “we may not be able to link cause to effect” (Van de Wiel and Coulthard, 2010, p. 90). This conclusion is reached through the identification of self-organized criticality in fluvial systems (Van de Wiel and Coulthard, 2010). Van de Wiel and Coulthard’s modeling research focuses on bedload transport but many alluvial archives are based on fine-grained overbank sediments, where over centennial and millennial timescales in Europe the impact of anthropogenically increased sediment load on river systems has been demonstrated (Notebaert and Verstraeten, 2010).

The current state of research into distinguishing fluvial drivers is likely to fall between the two opinions expressed above. The future research agenda will be focused on quantifying the relative impacts of autogenic and allogenic drivers through combined alluvial stratigraphic and modeling approaches, the latter including landscape, hydrological, and flood hydraulic models. Furthermore, an essential prerequisite for deciphering past (centennial scale) drivers of fluvial system change are sound geochronologies and while it is beyond the scope of this article to go into detail about the AMS C-14 and OSL dating of alluvial sediments, it is important to mention the recent application of Bayesian age models in fluvial paleohydrology (Chiverrell et al., 2009; Thorndycraft et al., 2012). For example, Chiverrell et al. (2009) used a Bayesian approach to interrogate the chronology of terrace evolution in

the Ribble Valley (NW England), identifying contrasting chronological scenarios of river evolution, while also highlighting diachronous terrace formation along the valley, once again highlighting the difficulties of linking alluvial records to specific causal events.

Summary

To summarize, this article has covered some of the recent findings in sediment budget and paleoflood studies that quantify the impact of changing drivers on fluvial systems. Recent methodological advances, including the combination of LiDAR topographic surveys, geomorphic field data and modeling, have enabled greater spatial coverage and refined temporal resolutions enabling basin scale sediment budgets to be quantified (Brown et al., 2009) even for large rivers such as the Rhine (Hoffmann et al., 2009). The quantification of basin scale sediment budgets enables inferences to be made regarding the main drivers of change, including the role of autogenic processes. Paleoflood research in bedrock geomorphic settings highlights that the magnitude of extreme floods is responsive to past climatic variability, an interpretation not always readily available in alluvial settings. The future challenge for fluvial paleohydrology is to quantify allogenic and autogenic drivers and fluvial response, including flow hydraulics, over decadal to centennial changes at the reach scale so that the discipline can link to the aims of river managers (Sear and Arnell, 2006) and have a greater impact on river management strategies. To achieve this, future research will need to further integrate field stratigraphy, sedimentology, and geomorphology with landscape, hydrological, and hydraulic flood modeling.

Introduction

Paleolimnology is the field of science that uses the sediments from inland waters to reconstruct past environmental conditions. Inland waters are variable and range from small shallow ponds to large lakes, from standing waters of marshlands to faster flowing waters from large rivers, and from low conductivity freshwaters to athalassic (saline) lakes. Derived from the Greek *paleo* meaning ancient and *limno* meaning lake, paleolimnological studies provide the means by which it is possible to track how an environment has changed over time, even if no prior measurements exist for longer time scales, that is, hundreds to thousands of years ago. Recognition of the field has developed especially over the course of the past three decades, largely as a result of its explosive development as an applied science. Concern about the degradation of Earth's environmental conditions, largely as a result of the impact of human activities, has sparked an increased need for environmental assessments and the ability to effectively manage anthropogenic activity in a manner that is least detrimental to the environment. Studies focused on the natural development of environments address issues such as global climate change and other related topics, by providing an understanding of the natural cycle and the baseline conditions from which it is possible to discern which effects were caused by human activity and which were natural. Paleolimnological studies can help distinguish between the two. Underlying this research is the requirement to establish the extent of the impact being studied and the rate of environmental change. However, such studies are often hindered from the beginning, because in order to assess the state of current conditions it is necessary to have a perspective on how conditions have changed through time. In

the majority of examples, regardless of the time period being considered, data on background conditions do not exist. The instrumental record is short and in most instances might only exist on a decadal or centennial scale. For example, temperature records may exist for over 100 years in some cases, but these are rare. In the Canadian Arctic, ongoing temperature records only began in the late 1940s. The same applies in the case of acid precipitation. Many lakes have acidified within the last six decades, but no preimpact pH readings exist and in most cases instrumented environmental readings only exist for shorter periods, on the order of half a century or less. Paleolimnology provides the means by which past environmental conditions can be determined as paleolimnological techniques lengthen the instrumental record by using various proxy indicators of the environmental variable being investigated. With these longer records, baseline environmental conditions can be quantified and the natural variability of the system assessed. By reconstructing paleoenvironmental conditions, it is possible to address many topics concerning past and present-day conditions. From these it will be possible to better understand and predict future trajectories of environmental conditions on Earth. At a more immediate level, it is possible to use these data to derive best practices in the management of an environment so as to maintain its ecosystem services. Policy development concerning environmental management is one of the more tangible and rewarding aspects of paleolimnological research.

Although paleolimnology has advanced gradually as a discipline, it is now a rapidly progressing science, reflecting the development of novel tools and applications. The roots of paleolimnology can be traced to DeGeer's study in the late nineteenth century of seasonal sediment deposition in Swedish

lakes (Wright, 2010). Early paleolimnological studies, dating back to about 1920, were largely descriptive (Frey, 1988); however, tremendous advances have been made over the ensuing decades and have transformed the science to one that is quantitative, applied, and still expanding (Birks, 1998; Smol, 2008). This is largely due to the coincidental timing of a serious environmental problem, namely acid precipitation, and the development of personal computers (PCs;) (Battarbee, 1991). Acid precipitation was affecting lakes and paleolimnology was the science responsible for addressing this problem. The increased computing power that PCs provided allowed for the development of computationally complex multivariate analyses that could be applied to other environmental challenges, such as climate change and eutrophication. While early studies mostly focused on one primary proxy indicator, the importance of multiproxy studies has been recognized and it is now typical for multi-investigator, multiproxy international research studies to be undertaken. Paleolimnological developments have been rapid and significant over the last three decades.

The first international paleolimnology symposium was held in 1967. Following its success and subsequent meetings, the International Paleolimnology Association was formalized in 2006 (proposed in 2003). An early compendium of related articles (Haworth and Lund, 1984) provided one of the first collections of paleolimnological papers. Several scientific journals and series (e.g., *Journal of Paleolimnology* and *Developments in Paleoenvironmental Research*) are dedicated to syntheses of paleolimnological methods (e.g., Francus, 2004; Last and Smol, 2001a,b; Smol et al., 2001a,b) and regional data (Battarbee et al., 2004; Pienitz et al., 2004). In-depth textbooks have focused on the scientific applications of paleolimnology and are useful to students at the senior undergraduate and graduate levels (Berglund, 1986; Cohen, 2003; Smol, 2008).

Lake as Archives

Lakes are archives of past environmental conditions, as their sediments represent an accumulation of biological, chemical, and physical components originating from within and without the lake (Figure 1). Materials making up the sedimentary matrix can be divided into one of two groupings: constituent material originating from within the lake itself is termed autochthonous, whereas material originating outside the lake, such as in its watershed (catchment) or air shed, is referred to as allochthonous. Sediment components can be further subdivided into biological, chemical, and physical groupings. These are described in greater detail below and as separate articles in this encyclopedia (see Table 1). Over time, as sediments buildup, a time–depth relationship is established with older sediments underlying younger sediments, as per the Law of Superposition. Through the use of a sediment corer, it is possible to recover a vertical column of sediment that represents past periods of deposition. By obtaining deeper sediments it is possible to sample farther back in time. Figure 1 illustrates a hypothetical example of how sediments from a lake formed in a glaciated terrain might be able to capture past environments. In this example, the lake formed following deglaciation of the region and the sediments captured the glaciolacustrine nature of the early lake through the

Figure 1 Idealized diagram of a typical progression of events within a postglacial lake and watershed, captured within lake sediment stratigraphies. Deglaciation is first followed by a natural succession of vegetative types, leaving pollen and other remnants behind in the sediment. Agricultural activities introduce modified and/or exotic vegetation and enhance sediment and nutrient runoff from within the watershed. Finally, urbanization and industrialization typically introduce unique, unnatural materials into watersheds, including many forms of organic contaminants, inorganic acids from atmospheric fallout, combustion residuals (soot and metals), and so on. A record of each of these watershed events may be found in the sediment sequence of lake sediments in their order of progression.

various steps of landscape evolution (tundra, forest, and human-induced changes of agriculture and urbanization). From the time of their inception, lakes start accumulating sediments and hence can serve as an archive spanning over several different time scales. For long-lived lakes whose sediments were not affected (or removed) by recent glaciations, for example, Lake Baikal (Russia), Lake Biwa (Japan), and African Rift Valley lakes, sediments have accumulated for millions of years. In areas that were glaciated during the last Ice Age, for example, large areas of North America and Europe, sediments usually represent only the Holocene or, approximately, the past 10 000 ka of accumulation. However, exciting new discoveries have been reported, concerning lakes whose sediments survived the ‘bulldozing’ effects or removal of previous glacial deposits in North America and Russia, including a 250 000-year record from Lake El’gygytyn in NE Russia (Brigham-Grette et al., 2007) and a 200 000-year record from Baffin Island, Canadian Arctic (Axford et al., 2009). These long and continuous records are shedding new light upon the most recent preglacial history of these continents, in light of the effects of global warming which are magnified at higher latitudes.

The Paleolimnological Method

Paleolimnological studies require a series of sampling and analyses, with each requiring varying degrees of expertise

(Figure 2). Termed the paleolimnological method, it includes several steps, starting with the retrieval of a sediment core. Once retrieved, a core is sectioned, either on site or back in a laboratory, into subsections which are partitioned for various analyses including chronological dating, and geochemical, physical, and biological or proxy indicator analyses. From the generated data, multivariate analyses are used to reconstruct the environmental condition being investigated. More often than not, a completed paleolimnological analysis will enlist the use of a variety of laboratories, each specializing in one or more of the steps.

Figure 2 The paleolimnological method. Major steps involved in conducting a paleoenvironmental assessment are as follows: (1) A sediment core is retrieved from a lake and subsectioned into discrete intervals (typically 0.25–1.0 cm) (2) for dating and proxy analyses. The thickness of the sampling interval determines the temporal resolution of the final results. Thinner subsections (0.25–0.5 cm) represent shorter time intervals but also require more time and expense to process the added number of samples. It is common for researchers to sample cores finely near the surface and more coarsely downcore in order to capture recent events with the best possible resolution while also acquiring adequate information about longer-term background or natural conditions. Subsections are then further divided and typically shipped to separate laboratories for analysis of dating parameters, such as ^{210}Pb or ^{137}Cs ; (3a) geochemical analyses, such as mineral composition, total carbon, and so on and (3b) for analyses of specific proxy indicators such as diatoms, pollen, and chemical contaminants. (4) The results from the dating analyses and modeling are then combined with those from the proxy indicators to create a detailed history of each proxy indicator examined within the lake sediment. (5) Results from all of the independent proxy indicators are then combined and further analyzed using multivariate statistics to yield a comprehensive reconstruction of the history of events for the lake and its watershed.

Coring

The first step in the paleolimnological method involves retrieval of the sediment core. Particular attention must be given to this step, as it will be the basis from which the remainder of the study is established. The investigator must ensure that an undisturbed core, representative of the depositional environment, is recovered. Sediment stratigraphy must be intact, otherwise incorrect inferences will be made and erroneous conclusions drawn.

There are a variety of different coring devices available, each one suited to a particular type of lake and/or sediment type. [Glew et al. \(2001\)](#) describe the practice and various techniques needed to obtain an undisturbed sediment core from lakes of various depths. Similar to lakes, but facing its own challenges, peat coring methods have been described by [de Vleeschouwer et al. \(2010\)](#). Over a dozen different kinds of corers exist, many

Figure 3 Examples of three commonly used corers: (a–d) gravity corer: (a) A gravity corer with an open breach is lowered down through the lake water slowly into the lake sediment (b). Once seated in the sediment at the proper depth, a weighted messenger is dropped down the coring line in order to trigger a plunger that seals the top of the core (b) and (c). Sealing the top of the gravity core creates a suction that holds the lake sediment within the sampling tube until the core is retrieved to the lake surface (d). (e–g) Freeze corer: A frozen finger (freeze core) is filled with dry ice and ethanol and lowered into the sediment to an appropriate depth (e–f). The core is left in the sediment until a coating of material freezes firmly to the outside of the casing (f). The core is then retrieved to the surface with a representative stratigraphy frozen to the outside casing. (h–j) A piston corer uses suction in the same manner as a gravity corer to capture sediment within a section of core tube. Typically deployed from a stable ice platform (h), a rigid set of tubes is lowered close to the sediment surface (i). The core tube (b) is then forced past the flange tip (a) of the corer by means of a push rod (c) into the sediment (j) while the tip remains locked in place with a control cable (d). Once the core tube has been pushed to its furthest extent into the sediment, the assembly is retrieved to the surface for subsampling. A rigid casing is periodically used to guide piston cores into place through the water column (h) and piston cores may be deployed and retrieved sequentially in order to create one continuous record for the entire sediment stratigraphy.

of which are common, albeit on a smaller scale, to the corers used in oceanographic studies. Each one is designed to retrieve an undisturbed sediment core from lakes of various types. [Figure 3](#) illustrates three commonly used sediment corers in lakes: gravity, freeze, and piston corers. Each one is best suited to a particular kind of lake and sediment. Sediment corers are usually deployed from either a boat or floating platform, or in cases where a lake may freeze over seasonally, from an ice platform ([Figure 4\(a\)](#) and [4\(b\)](#)).

Gravity corers, as the name suggests, use the force of gravity to penetrate the uppermost sediments. The corer, often composed of a sturdy metal such as brass or stainless steel, houses a plunger that can seal the top of a clear plastic or polymer tube. The corer is slowly lowered through the water column, so as to prevent the formation of a bow wave that would disturb the sediment–water interface. The mass of the corer should be sufficient to help force the tube into the sediments. Care must be taken not to overshoot and completely bury the corer and core tube in the sediments, as the sediment–water interface represents the present-day conditions and is an important reference point for the core. Once the person deploying the corer is certain that the corer has settled into the sediment, a messenger (i.e., a small weight) is deployed down the core line to trigger the plunger. The plunger seals the top of the core tube

Figure 4 (a) Typical coring platforms can include two canoes lashed together or (b) the frozen ice surface of the lake. (c) The sediments recovered by gravity coring exhibit color changes reflecting different sediment matrices or (d) fine laminations as recovered from a varved lake. Picture photo credits: (a)–(c), M. Douglas and (d) S. Lamoureux.

so that the corer and sediment core can be pulled up to the surface of the lake. Before breaking the surface–water interface, a bung (often made of rubber or closed cell foam) must be inserted at the base of the core tube to plug it and prevent any sediments from falling out. If deployed correctly, these sediment cores will reliably collect an intact sediment–water interface and the underlying sediments, up to 1 m or so in length, depending upon the nature of the sediment matrix and the length of the core tube. Gravity cores are especially well suited for studies that focus on the recent past (the past few centuries or less). So long as the sediments are not too compacted, for example, clays or sand, cores can be successfully obtained.

Frigid finger or frozen coring is specialized and more complicated than gravity coring. In this case, sediments are brought to the surface after having been frozen *in situ*. The corer consists of a box or tube that has been sealed at one end. This end is

either wedge-shaped or conical and has been weighted, often with lead. The corer is then filled with dry ice and ethanol and lowered gently into the sediments where it remains for roughly 5–7 min, depending on the ethanol–dry ice charge, while the sediments freeze to the outside of the corer. The carbon dioxide gas, generated from the dry ice, escapes via a small vent at the top of the corer. Upon retrieval at the surface, the corer and its rind of frozen sediments (usually about 1 cm thick) are separated and the frozen sediment is transported and stored in a freezer prior to further analyses. This kind of coring does not recover large amounts of sediments, but it is especially useful in lakes where the sediments are very loosely consolidated yet finely structured. For example, the sediment of meromictic lakes is often varved (annually laminated). Freezing these sediments *in situ*, as described, preserves these laminations. Again, depending upon the nature of the sediment and length of the

coring apparatus, it is possible to retrieve sediment cores up to 2 m or more in length. Generally, however, shorter cores are obtained. The specialized nature of this coring technique restricts its use to a certain extent. Because of transport regulations regarding dry ice (effectively, solid carbon dioxide), it is difficult, although not impossible, to use this technique in very remote areas.

Piston coring is used when obtaining longer sedimentary sequences. The coring apparatus consists of a tube, which is connected to a handle at the top by a series of rods. Inside the tube is a piston, connected to the top of the device by a strong wire cable that can be positioned at either end of the tube. With the piston positioned at the leading end of the core tube, the corer is pushed into the sediments using the rods, until it is directly above the sediment sequence to be recovered. The piston is then locked into place by securing its connecting cable in place with a clamp, and the core tube is then pushed 1 m down past the piston. This results in a core tube filled with sediment that is brought back to the surface of the lake by pulling up the rods. Another core tube is attached, and the process is repeated for the next depth interval. Generally, a researcher will work downward through the lake sediments, sequentially recovering 1 m of core at a time until an impenetrable layer is met. In order to ensure that a continuous sediment sequence is obtained, and no depths remain unsampled, the researcher will overlap the core intervals so that there are a few centimeters of overlap between the bottom of one core section and the top of the next lower interval. Because of problems with rigidity and strength of the rods, casing is often used to guide and constrain the rods and the attached corer back to the same core hole. In addition, there is a limit to the length of the core sequence that can be obtained. A combined length of water depth and rod length of no more than 20 m is generally the maximum. Piston cores have been used to obtain entire postglacial sequences (up to 11 m or more) in some lakes.

The three methods described can be used on relatively small lakes and require little logistical support. The equipment can even be transported by a coring team to remote areas without mechanical assistance. However, core retrieval from the larger lakes of the world, such as lakes Biwa, Baikal, Titicaca, Great Salt Lake, and even the Laurentian Great Lakes, require much more logistical planning and equipment. Thus, for a long period, these lakes remained uncored. Recent design advances and a concerted push by the paleolimnological community have resulted in long, multimillion-year cores being obtained. In some instances, drilling crews similar to those used on oil rigs are employed to recover the cores (Dean, 2010). Drilling platforms can be deployed from specialized drill ships, such as those used by oceanographers, or from ingenious platforms designed for easy transport and deployment on these large, yet often remote, sites. The challenges and problems associated with these designs and large projects are described by Leroy and Colman (2001). The efforts however, are rewarding as long, millennial-scale core records can be obtained. This is of especial interest to long-term global change studies.

Subsectioning

Upon retrieval of a core, it is extruded and subsectioned into intervals so that the sediments can be partitioned for various

subsequent analyses. This can be done on site, immediately upon retrieval of the core, or it can be completed back in the more controlled conditions of a laboratory. The decision is based upon the nature of the sediments, the kind of core, as well as the location of the coring site. Frozen cores are transported intact, back to a freezer and laboratory, until further analyses. Gravity cores can be subsectioned on site, especially if the sediment matrix is loose and unconsolidated and/or if during transport back to the lab there is a likelihood of the sediments getting mixed. Piston cores are usually returned back to the lab in 1 m sections, where they are split lengthwise. One half is preserved for the archives and the other working half is subsectioned, as necessary.

Dating Analyses – Geochronology

Once a sediment core has been retrieved and the researcher is assured that the core represents an unmixed stratigraphic column of sediments, the age–depth relationship can be used in the reconstructions. Establishment of a reliable, accurate chronology is key for all temporal interpretations. According to the Law of Superposition, younger sediments will overlie older, deeper sediments. This is the basis of relative age dating. In most instances, an absolute chronology is desirable so that specific dates can be linked to past events. Paleolimnologists have a number of dating techniques at their disposal to help resolve depth with respect to time. Each is appropriate for a certain age range and sediment type. These are covered in detail in the dating article and articles in Last and Smol (2001a). For events that have occurred within the past 150 years, ^{210}Pb and ^{137}Cs radioactive isotopes are commonly used. Another radioactive isotope, ^{14}C , has been used to date lake sediments up to roughly 50 000 years of age. Accelerator mass spectroscopy dating extends this age limit and new developments are refining dating chronologies. Other dating techniques include electron spin resonance, paleomagnetism, luminescence dating, varve chronology, amino acid racemization, tephrochronology, and marker beds of pollen, such as *Ambrosia*, that can reflect specific events such as European settlement of eastern North America. In a similar approach, Rose and Appleby (2005) demonstrated how a rise in spheroidal carbonaceous fly-ash particles could be dated to 1850 ± 25 years, for lakes within the United Kingdom.

Proxy Indicator Analyses

Proxy indicators are isolated from the sediment matrix and analyzed so as to infer past environmental conditions. These can be subdivided into three groups, namely, biological, physical, and geochemical. A brief review of these indicators is provided below. Table 1 lists some of the more commonly used proxies and references specific dedicated entries within this publication (*Encyclopedia of Quaternary Science*) which provide a more detailed account of each proxy. While early paleolimnological studies were based solely upon one main proxy indicator, multiproxy studies employing several biological, geochemical, and/or physical proxies are now common practice, as they yield more robust and holistic reconstructions.

Biological indicators

In order to be used as a paleoindicator, also known as a proxy indicator, a biological proxy must possess several important

characteristics. It needs to reproduce quickly, be abundant, easily and consistently identified, readily preserved in sediments, and ecologically constrained to specific environmental conditions. Ideally, the proxy contains either durable 'hard' parts or resilient 'soft' components that do not easily decompose and are readily identified through microscopy or geochemical analyses. Numerous biological indicators are used in paleolimnological analyses to infer past conditions. The remnants of these living organisms are preserved within lake sediments as morphologically identifiable 'hard' parts, that are usually derived from the organism's body, and are easily enumerated using microscopy (such as light microscopy – 5–1000 $\times$ magnification – or scanning electron microscopy for higher magnifications at the sub- and micron level). Many of these cell walls or hard parts are composed of chitin (e.g., insects), biogenic silica (e.g., diatoms and chrysophytes), calcium carbonate (e.g., mollusks), cellulose (e.g., desmids, plant macrofossils), or other biopolymers such as sporopollenin (e.g., pollen grains). Examples of these proxies include algae (diatoms, chrysophytes, and desmids), plant macrofossils, zooplankton, mollusks, and insects. Others are preserved as biochemical remnants derived from their 'soft,' organic parts such as pigments and biomolecular signatures derived, for example, from alkenones and DNA fragments preserved in sediment. These so-called biomarkers are compounds that can be traced to a source organism or process (Castañeda and Schouten, 2011) and require biogeochemical analyses for their identification. Biomarkers have been established for numerous organisms, including green algae (botryococenes), cyanobacteria (heterocysts and glycolipids), bacteria (bacteriopheopigments, BHPs), and for processes such as photosynthesis and biomass burning (Castañeda and Schouten, 2011).

The use of biomarkers is increasing as new techniques for isolating various biochemical components are being developed. Not only is the taxonomic catalog of biomarker signatures increasing, but a new understanding of organisms' distribution is expanding. D'Andrea and Huang (2005) reported the discovery of long-chain alkenones (LCAs) in a sediment core and surface sediments of Greenland lakes. This discovery confirmed the presence of prymnesiophyte (haptophyte algae), that had not been previously reported using conventional light microscopy methods. A similar survey of prairie lake surface sediments from Canada established the presence of LCAs and confirmed that haptophytes typically inhabit sulfate-rich, saline lakes (Toney et al., 2011).

The identification of these specific biomarkers is helpful in cases where the hard, morphological remains of a proxy have not been preserved. For example, in situations where taphonomic processes such as dissolution removes diatom frustules, measurements of the diatom biomarker, loliolide, can provide the missing diatom abundance data, although not at a species level (Castañeda and Schouten, 2011). Identification at the species level can be attained through analyses of fossil DNA fragments, and although much further work remains in cataloging the DNA signature of living organisms and distinguishing this from the fossil signature (Castañeda and Schouten, 2011), some advances have been made. For example, Theroux et al. (2010) used DNA fingerprinting to resolve the issue of species identification in their study on the diversity of lacustrine haptophytes (prymnesiophytes). The presence of alkenones confirmed the presence of haptophytes, but

genetic analyses were needed for identification to species level. This has important implications for alkenone temperature calibrations, which are useful for paleoclimatic reconstructions, yet are best applied to know species assemblages.

Many of these proxies and their derivatives, such as algae, zooplankton, mollusks, and sponges, originate from within the lake (autochthonous) and can be used to reconstruct water chemistry and microhabitat availability throughout the core sequence. Others are transported into the lake from outside the lake (allochthonous) via wind and water currents, and stored within the sediment archives. Allochthonous proxies, including pollen, phytoliths, and insects, can be used to track vegetation shifts and infer past climate variables, including temperature and precipitation, as well as ecosystem dynamics.

The value of an indicator lies in the paleolimnologist's ability to quantify the organisms' environmental optima and tolerances. In so describing each taxon's environmental niche, or space, it is therefore possible to link its occurrence in a stratigraphic profile to specific environmental conditions. Until recent advances in appropriate multivariate statistics, precise quantification of these environmental optima and tolerances was rare and difficult. This calibration of indicators to environmental conditions or variables is achieved by using surface-sediment training sets and is described briefly here and in detail by Birks (1995), Birks et al. (2012), and Smol (2008).

Physical and geochemical indicators

Examination of the physical and chemical sedimentary matrix has revealed a large number of sources for determining paleoenvironmental conditions, including paleoclimates and other past environmental conditions. Table 1 lists some of the more commonly used indicators and some of their applications. These include bulk density, grain size, mineralogy, and magnetic susceptibility.

Progress in analyzing stable isotopes preserved in lake sediments has been rapid over the last decade and is described in the recent literature (Ito, 2001; Leng et al., 2006). Using different sediment fractions, that is, biogenic, precipitate, and so on, various stable isotope ratios can be measured to reconstruct past water chemistry variables (Table 1). These can be related to paleoclimatic conditions. Oxygen, carbon, nitrogen, and hydrogen isotopes from lacustrine sediments contribute to paleoclimate reconstructions; however, a detailed knowledge of processes controlling their abundance is necessary, as even small differences in temperature can cause, for example, a shift in their equilibrium (Leng et al., 2006). Oxygen isotopes are measured from inorganic and organic samples and are used in paleoclimatic reconstructions. Other information on productivity and changes in nutrient supply are obtained from carbon and nitrogen isotopes measured from organic materials in lakes. Isotopic studies are well suited for multiproxy studies as interpretation based solely on isotopes is unconstrained and hence limited.

Data Analyses and Quantification

One of the greatest advances in paleolimnology has been in data analyses leading to the quantification of environmental change and paleoenvironmental assessment. This big step brought paleolimnology forward from a descriptive to a

quantitative science. It then became possible to test hypotheses and quantify environmental responses to ecological perturbations. As indicated by Birks (1998, 2008), Birks et al. (2012), and Smol (2008), the creation of modern surface-sediment calibration or training sets conferred strength and rigor to paleolimnological studies that had previously been lacking. By linking biotic assemblages with their associated environmental data, it is possible to quantify species–environmental relationships. The modern training set is constructed by undertaking a field-intensive regional survey of approximately 50 lakes. From each site, the surface sediments (top 1 cm) are collected and the physical and chemical water chemistry is measured. Two data matrices are then developed from these sample collections. The first is composed of the abundance of the biological proxy indicators in question for each site, for example, diatoms (can include several hundred species). The second matrix consists of the physical and chemical characteristics for each site. Often relative abundance measurements are used. Using multivariate analyses, for example, such as multivariate regression and canonical correspondence analyses, it is possible to identify which environmental variables are contributing the most to the observed species distribution. Once each species' environmental optima and tolerances are calculated, it is possible to construct transfer functions that relate species' abundance throughout a stratigraphic sequence to quantitative values of the environmental variable being reconstructed. A simplified description of the process is provided by Smol (2008).

As longer and finer-resolution stratigraphic records are obtained, it is possible to conduct time-series and rate-of-change analyses on stratigraphic paleolimnological data (Birks, 1998; Birks et al., 2012). Innovative developments in numerical and statistical techniques are providing answers to complex questions. This is especially true of the capacity to handle the large amounts of data generated by multiproxy studies.

Paleoenvironmental Assessment: Paleolimnological Applications

Paleolimnology has developed into a science with a broad spectrum of applications. These range from describing long-term trends in climate change to helping solve environmental crises caused directly or indirectly by anthropogenic activities. Paleolimnological analyses have been conducted on every continent and at nearly every possible latitude on Earth, where lakes or paleolake sediments exist. Paleolimnological analyses have also been proposed by exobiologists for potential work on other planets, including Mars (Doran et al., 2004; Lim and Cockell, 2002). This section provides a brief overview of some of the diverse studies that use paleolimnological applications and makes reference to additional articles in the encyclopedia.

Some of the most important applied paleolimnological work has focused on the human-induced problems of acid precipitation and eutrophication. In both instances, success has largely been due to the usefulness of diatoms in tracking these changes. Diatom species–environment responses are strong along pH and nutrient gradients and hence the sensitivity of this proxy to changing environmental conditions is remarkable. Reviews of these environmental problems are detailed by Smol (2008).

It is possible to track the source of nutrients and pollutants to a lake via various vectors, using paleolimnological techniques. Surprisingly, even very remote lakes are experiencing the consequences of elevated nutrient and pollutant levels. These vectors include animals (zoological vectors), atmospheric currents, and runoff. Some salmon species' life cycles make use of nursery lakes for spawning purposes. Because adult salmon spend most of their time in the ocean, their flesh is enriched in ^{15}N and this can be used as a convenient paleolimnological signal that identifies the source of nutrient additions to freshwaters, of a marine origin. Decomposing adult carcasses add nutrients elevated in ^{15}N to these lakes. Using a combination of ^{15}N isotopes and diatoms, it is possible to reconstruct the long-term population dynamics of these fish populations over several millennia (Finney et al., 2002). In a parallel study of decomposing whale carcasses, elevated levels of ^{15}N and diatom-inferred nutrients were used to track past human occupation (Thule Inuit) of a High Arctic wintering camp for four centuries (AD 1200–1600; Douglas et al., 2004). In the Antarctic, Hodson and Johnston (1997) examined sedimentary seal hairs to track changes in seal populations. In a subsequent paleolimnological reconstruction, fluctuations in historical seal populations could be linked to human harvesting activities such as whaling and sealing. This information is useful for the development of conservation policies on how to deal with recent population increase in fur seals that threaten nearby freshwater aquatic ecosystems (Hodson et al., 1998).

Muir et al. (2009) measured the spatial and temporal distribution of atmospheric deposition of mercury in surface sediments across eastern North America and found a significant trend of deposition of mercury into the isolated Arctic. Wolfe et al. (2001) documented the ecological changes in alpine lakes, in the Rocky Mountains of Colorado, induced by anthropogenic atmospheric nitrogen deposition. The high elevation lakes' algal assemblages were sensitive to the added input of nitrogen and this left a sedimentary signal. Blais et al. (2005) tracked elevated levels of nutrients and pollutants such as persistent organic pollutants (POPs) that were being transported from the ocean environment back to Arctic lakes and ponds via seabirds that were feeding in the adjacent marine system. The POPs had been transported via air currents to high latitudes. In a complementary study, Michelutti et al. (2010) demonstrated how trophic position influenced the levels of metal pollution. Two seabird species that feed from different trophic levels (planktonic fish and invertebrates vs. benthic mollusks) transported different metals derived from their marine food sources back to lakes, thereby providing a means by which particular metals could be used to reconstruct past seabird populations. Zale (1994) used the elevated levels of phosphorus and copper in Antarctic lake sediments to determine past penguin rookery populations. These birds were bioconcentrating nutrients and metals from their marine diet of krill, and some of their guano was leaching into a nearby lake. Sun et al. (2000) conducted a similar study and inferred penguin population fluctuations in response to shifting climatic conditions over the past 3000 years.

Paleolimnological studies have been used to study long-term environmental climate change. Kashiwaya et al. (2001) reconstructed major climatological and limnological changes for the past 3.5 million years of Lake Baikal, Russia. They related

physical properties of the core to the effects of Milankovitch orbital parameters. Using diatoms as the main proxy indicator, [Laird et al. \(2003\)](#) reconstructed the drought intensity and frequency for the past two millennia of the Northern Great Plains of North America by tracking diatom-inferred lake water salinity. Reported at subdecadal resolution, these data identified droughts that lasted for centuries and were related to the same atmospheric circulation anomalies causing modern and potential future drought. The historical perspective provided by these paleolimnological studies has demonstrated the susceptibility of western and central Canada to the effects of warming climates: during drier periods in the past, lake basins closed, resulting in increased salinity and eutrophication ([Schindler, 2009](#)).

[Bigler and Hall \(2003\)](#) were able to directly link diatom assemblages as quantitative indicators of temperatures at a century-scale in northern Sweden. New advances in oxygen isotope measurements are providing the potential for direct temperature inferences from diatoms. [Crespin et al. \(2010\)](#) reported that the temperature-dependent relationship between the $\delta^{18}\text{O}$ value of diatom frustules and lake water is a promising tool for reconstructing paleotemperatures. Recent advances on the uses of biomarkers are contributing toward the reconstruction of past temperatures as well. [Pearson et al. \(2011\)](#) report on the use of glycerol dialkyl glycerol tetraethers (GDGTs) derived from Archaea and bacteria in lake sediments. A calibration of GDGTs from the surface sediments of 90 lakes distributed across a transect from the Scandinavian Arctic to the Antarctic yielded a root mean-squared error of 2.0°C and demonstrated the potential of this chemical proxy as a useful tool for paleothermometry.

Lake sediment analyses contribute important data to large projects such as those defined by large international collaborative efforts. The IGBP-PAGES PEP III (Pole–Equator–Pole) is one such project. Focused on the paleoclimate change of the last 200 000 years in a transect that crossed Africa and Europe, paleolimnological studies were the most common analyses used ([Oldfield and Thompson, 2004](#)) and included studies of sea-level change on the Scandinavian coast ([Hedenstrom and Risberg, 1999](#)), paleolakes of the Sahara ([Gasse et al., 1987](#)), as well as many others. The net result of these efforts was a better understanding of climate variation throughout this long transect, as well as the interactions between humans and climate over this same time period through Europe, the Middle East, and Africa. The complexities of the interactions between the Eurasian ice sheets, the North Atlantic circulation, and tropical monsoons, for example, were illustrated, and although additional research is required, the long time-series recoverable from many of these geographic areas means that answers will be forthcoming.

Paleolimnological studies from across the continents indicate a consistent climate record during the Holocene: moist conditions (high lake levels) during the early Holocene and a subsequent drying trend in the later Holocene. However, regional differences exist and can be refined by local studies. An overall picture of long-term changes can be extracted from these studies to tease out the orbital timescales that underlie the shorter term climatic variability ([Birks, 2008](#)). Compilations of regional climate syntheses have been completed for many regions of the globe. Paleolimnological

reconstructions, including those from ancient or seasonally present lakes, contribute important information to the overall picture of past climates. [Wünnemann et al. \(2007\)](#) examined climate instability for the past 45 000 years as recorded in Chinese desert lakes. [Vimeux et al. \(2009\)](#) performed an extensive investigation of past climates of South America. [Hodgson and Smol \(2008\)](#) and [Pienitz et al. \(2004\)](#) compiled a synthesis of documented environmental change at high latitudes. As predicted by general circulation models, these high latitudes are already exhibiting the effects of a warming climate. In one example, the effects of this recent warming were documented across a circum-arctic latitudinal gradient, based on a diatom and zooplankton study of lake sediments ([Smol et al., 2005](#)). Lakes at higher latitudes exhibited a markedly greater amount of warming than those at lower latitudes. [Fritz \(2008\)](#) discusses the challenges of reconstructing paleoclimates from the complex paleolimnological data derived from regional studies. Given the unique environmental conditions of any lake, a nonlinear response to climatic forcing can occur, resulting in spatial heterogeneity in the timing of inferred change. In order to assess climate at longer temporal scales, including multidecadal, it is important to synthesize large data sets from which patterns of local climate response can be separated from broad, regional scale patterns.

Paleolimnology is playing an important role in bettering our understanding of natural hazards such as tsunamis. Often resulting from earthquake activity, tsunamis generate run-up waves that can inundate coastal areas and hence leave a signal in coastal water bodies. [Hutchinson et al. \(2000\)](#) identified layers of sand in the sediments of a lake situated at the head of a fiord on western Vancouver Island, Canada. These three tsunami events were followed by a fall in relative sea level, confirmed by analyses of protozoan and diatom microfossils. In the Shetland Islands, [Bondevik et al. \(2005\)](#) identified three sand layers in sediments of coastal fens and lakes dating between 8000 and 1500 years ago. The oldest layer could be related to a tsunami generated by a well-studied landslide on the Norwegian continental slope which would have generated a wave of over 20 m. [Pisaric et al. \(2011\)](#) documented the impact and limited recovery of coastal lakes from a storm surge event in 1999 in the Mackenzie Delta, Arctic Canada, using diatom-based paleolimnological techniques. This long-term perspective showed that the extent of the storm surge was unmatched over the past 1000 years and was likely a signal of a higher probability of future surges, due to the impacts of a warming climate and rising sea levels. Knowledge of the frequency of past tsunamis and smaller storm surges is important to improve our understanding of their impacts and the subsequent recovery of coastal environments.

Environmental management practices and policies are increasingly relying on paleolimnological data to provide the reference baseline conditions that need to be met in order to return an ecosystem back to its natural (preimpact) conditions. [Salgado et al. \(2009\)](#) conducted paleolimnological analyses of aquatic macrophytes (macroremains) to determine the predisturbance communities in Loch Leven, Scotland. They established the reference state characterized by soft-water macrophytes and noted that in order to return to preimpact conditions, nutrient reduction to the lake would have to be effected.

Lakes provide a range of ecosystem services to those communities living within their catchments and, in certain instances, where multiple stressors have negatively affected these services, such as food security (provisioning), trade-offs are necessary in order to ensure environmental and/or economic stability. Tropical Lake Victoria in Africa provides such an example of a lake which has experienced rapidly expanding human population growth and changes to agricultural practices. Changes in land-use practices are contributing high nutrient loading into the lake, and this eutrophication is affecting the aquatic ecosystem, threatening the survival of an endemic fisheries population that supports the large human population living within its catchment. [Verschuren et al. \(2002\)](#) conducted a multiproxy paleolimnological study to reconstruct past limnological conditions and confirm the cause of fisheries decline. By examining sedimentary pigments, diatoms, and chironomid remains, they identified the periods of eutrophication and subsequent anoxia that developed in conjunction with human population growth. Deep-water anoxia affected the habitat of certain fish species, resulting in a fisheries collapse and a need for an improved management of land-use practices. In a similar study from Loch Leven, Scotland, [May and Spears \(2012\)](#) used paleolimnological reconstructions to provide environmental managers with key background conditions from which to develop effective policies for conflicting ecosystem service activities including pollution and flood control, fish stocking, and recreation and nature conservation.

Paleolimnological studies are not restricted to sediments from lakes or paleolakes. Large river systems have been successfully cored and yielded stratigraphically intact sediment cores whose data could be applied to tracking environmental changes and subsequent management decisions. [Reavie et al. \(1998\)](#) inferred past shoreline characteristics from sediment cores obtained from fluvial lakes within the large St. Lawrence River, Canada. The diatom transfer functions identified regions whereby water quality had improved, following management decisions to restrict nutrient runoff. These abatement measures decreased macrophyte density nutrient levels. In a second example, [Reavie et al. \(2005\)](#) used diatom and geochemical data (metals) to track environmental degradation in the St. George River draining Lake Superior, Canada. A sediment core obtained from this fluvial lake faithfully recorded the effects of anthropogenic activities such as logging and dam-building, as well as the effects of the steel-, leather-, and paper-manufacturing industries.

Recent advances in drilling hard-to-reach lakes, such as the subglacial lakes in Antarctica, hold great promise of yielding important information on the genesis, longevity, and biological flora and fauna of these isolated ecosystems. Recent efforts to drill through several kilometers of ice to reach the waters of Lake Vostok (up to 4 million years old) and Lake Ellsworth (up to 400 000 years old) provide the opportunity to retrieve sediment cores that will add to our understanding of the history of the East and West Antarctic Ice Sheets, respectively ([Gramling, 2012](#)).

New Developments/Conclusions

Paleolimnology is continuing to develop at a rapid pace. It is clear that the footprint of humans on the environment is not a

delicate one and that environmental managers will continue to rely heavily on this branch of science. Paleolimnology has now established a central role in determining the water framework for many nations ([Dalton et al., 2009](#)). As new environmental proxy indicators are described and calibrated, and new analytical techniques are developed, our understanding of complex environmental interactions will increase. The description and development of new proxy indicators, especially biomarkers, are refining the types of questions that can be resolved and a more holistic reconstruction of past environments will be possible.

New developments in acquiring quantitative data nondestructively are enhancing paleolimnology's ability to infer past environments. Information from digital images of cores can be applied to a number of different research questions ([Francus, 2004](#)). Image analysis is rapid, relatively inexpensive to obtain, and can be applied to a wide range of data. Because digital photography can yield high-resolution images, methods for counting and identifying fossils, such as pollen and calcareous microfossils, are being refined. These methods can greatly assist in studies in which numerous samples are processed. New numerical and statistical methods are providing powerful, complementary tools that will aid in the interpretation of multiproxy studies. These are key to deciphering changes at interannual and decadal scales and modeling biological dynamics.

As paleolimnological studies deliver higher temporal-resolution interpretations, a better understanding of neolimnological processes is becoming possible. [Saros \(2009\)](#) describes how the interface of neo- and paleolimnology is yielding a better understanding of mechanistic links of species–environment relationships. These long-term, high-resolution data are critical in the management of ecosystems and to our understanding of ecosystem resilience to current and future environmental change, such as global warming ([Willis et al., 2010](#)).
